ABSTRACT

With the development of inflatable technologies, inflatable structures used as large space antennas are becoming very possible for near term space missions. This paper discusses the development of an inflatable/self-rigidizable structure for a three-meter Ka-band reflectarray antenna. This reflectarray antenna uses “beam scanning reflectarray antenna with circular polarization” technology. This technology uses a flat surface instead of a parabolic surface to be the Radio Frequency component. A flat "natural" thin-membrane surface is much easier to accomplish and maintain than a curved "non-natural" parabolic surface. An innovative inflatable/self-rigidizable technology, namely "Spring Tape Reinforced (STR) aluminum laminate boom", has been developed by this research. STR aluminum laminate boom automatically rigidizes after it is deployed with no space power, no curing agent, and no rigidization system is required. Any small damage caused by micro-meteoroids will not impact the membrane performance and inflation air is no longer needed once the antenna is inflated. Detailed mechanical design, dynamic analysis, and deployment demonstration of the antenna will be discussed by the paper.

INTRODUCTION

With the advancing of space sciences, larger and larger apertures with very low launching masses and volumes are demanded by space scientists for future missions. Space inflatable technologies will revolutionize future space structures and allow these demands becoming possible. Inflatable structures that used as supporting structures have been extensively investigated recently[1]. Major challenges include controlled deployment, space rigidization, dynamic modeling and simulation, etc. This paper will discuss the mechanical design and development of an inflatable Ka-band (32 GHz) reflectarray antenna[2]. The Radio Frequency (RF) component of this type of antenna is a flat membrane with hundreds of thousand of copper patches. The membrane is supported by an inflatable/self-rigidizable frame structure. Booms of the inflatable/self-rigidizable structure can be flattened. The flattened booms are rolled up on two mandrels and the membrane is rolled up a composite cylinder when the antenna is in stowed configuration. After the antenna is launched into space, it is inflation-deployed and the dynamics of the deployment is controlled by the deployment control system. Compare to other types of deployable antennas, this type of antenna offers very larger aperture with extremely lightweight and high package efficiency. The new antenna RF technology, namely beam scanning reflectarray antenna with circular polarization[3], made it possible to use a flat surface instead of a parabolic surface as the RF component. A flat "natural" thin-membrane surface is much easier to accomplish and maintain than a curved "non-natural" parabolic surface. It is also believed that a flat surface has better reliability for a long-term space mission than a thin membrane parabolic surface.

This paper starts from reviewing previous versions of the inflatable reflectarray antenna. Details of the current self-rigidizable model will then be presented. Functions and designs of several major components will be discussed. Ground deployment test and dynamic analysis of the deployed antenna will be presented. Future development directions of this type of antenna will also be discussed.

PREVIOUS RESEARCHES ON THE INFLATABLE REFLECTARRAY ANTENNA

American Institute of Aeronautics and Astronautics
The development of this technology was originated from a one-meter X-band model of the inflatable reflectarray antenna, which is shown in figure 1. The RF components of this unit are two layers of one-meter-diameter circular membranes that are supported by an inflatable structure. The inflatable structure is composed of a torus to support the RF membranes and a hexagonal ring to hold the feed. The torus and the hexagonal ring are connected by three struts. The inflatable structure is made of Urethane-coated Kevlar. Urethane-coated Kevlar is a very strong material for holding pressure. The RF membrane is made of Kapton. The weight of the inflatable structure is 0.74 Kilogram and the weight of the RF film is 0.27 Kilogram. The total weight of the whole antenna is only 1.08 Kilogram.

Upon the great success of the RF test of the one-meter inflatable antenna, a three-meter technology demonstration model of the inflatable reflectarray at Ka-band was also developed. The RF test results of the three-meter antenna demonstrated excellent radiation pattern characteristic. Figure 2 is the picture of the three-meter inflatable reflectarray antenna. The configuration of this antenna is like a horseshoe and its feed is supported by a hexagonal ring. The ring is connected by three asymmetrically located inflatable struts.

The reason to change the configuration from circular to horseshoe is that, after the inflatable structure is deflated, the membrane and the deflated structure can be rolled up onto the Rigid Tube Assembly without causing significant wrinkling to the membrane. Three struts, hexagonal ring, as well as the horseshoe frame (excluding the rigid tube assembly) is made of Urethane coated Kevlar and the weight is 3.92 kilograms. The single-layer RF membrane is made of Kapton and the weight is 2.55 kilograms. The rigid tube assembly is made of aluminum and the weight is 7.10 kilograms. The total weight of the antenna is only 13.57 kilograms.

However, this design still has several drawbacks. The first drawback of this design is that the feed and its amplifiers are placed far away from the spacecraft, which is located just below the antenna (nearby the center of the rigid tube assembly). These amplifiers will be difficult to protect thermally from extremely cold temperature in space. Vibration of the feed supporting struts is another drawback of this design. RF blockage introduced by feed supporting struts is also a drawback of this design. On the other hand, space rigidization is necessary for future real space missions. This configuration is not easy to accommodate current available rigidization technologies.

In order to increase the readiness level for space application, a design trade study for the three-meter inflatable reflectarray antenna has then been conducted. The “movie screen with offset feed array” was identified to be the best candidate for the reflectarray antenna structure. Based on the results of the design trade study, a new inflatable/self-rigidizable, namely “movie screen”, reflectarray antenna has been developed. The feed of this unit is offset located on the spacecraft and the reflectarray surface is deployed up by two inflatable booms. Figure 3 demonstrates the deployment process of the “movie screen” antenna. The inflation deployment process only involves the unrolling and pressurization of two inflatable booms. Compare to other mechanically deployed antennas, much less moving parts is employed by the inflatable structure.
Less parts not only means less weight and less development cost, it also implies better deployment reliability.

Figure 3. The Process of the Inflation Deployment

Figure 4 is the schematic of the “movie screen” inflatable reflectarray antenna. Major components include inflatable booms, RF membrane, flat panels, roll-up shells, cross bars, constant force springs, mandrels, end caps, catenary systems, etc. Detailed design consideration of each component will be discussed as following.

a) Inflatable/self-rigidizable boom technology

There is a major improvement of the “movie screen” antenna from the “horse-shoe” antenna. The “movie screen” antenna employed inflatable/self-rigidizable technology while the “horse-shoe” antenna only used inflatable technology without the rigidization.

Technically, the word “inflatable” means the structure is deployed by pressurization. After a structure is deployed, pressure still has to be kept inside the structure to maintain the rigidity of the structure. Due to the material imperfections and/or small damages caused by micro-meteoroids, small leaks are unavoidable. Large amount of make-up gas has to be carried to the space for a long-term mission, which is very costly or even not realistic.

With the development of space inflatable technologies, space rigidization is becoming a major research topic. Space rigidization, namely inflatable/rigidizable, is that a structure is rigidized upon the completion of its inflation deployment.

A new inflatable/self-rigidizable method, namely Spring Tape Reinforced (STR) aluminum laminate boom, has been developed by this research for the “movie screen” antenna. Compare to other rigidization technologies, STR aluminum laminate boom automatically rigidizes after it is deployed with no space power, no curing agent, and no rigidization system is required. Therefore, it is called self-rigidizable technology. Figure 5 is the buckling test set up of an STR aluminum laminate boom. Figure 6 is the picture of a 5-meter long STR aluminum laminate boom, which is rolled up on a 6.5 inches diameter mandrel. A typical STR boom consists of a tube that is formed with aluminum laminate. Four spring tapes are attached to the inside wall of the tube in axial direction. At this time, the commercially available stainless steel measuring tapes, commonly known as carpenter tapes, are used. With a wall thickness less than 0.1 mm, a STR boom can be easily flattened, rolled-up (or folded-up), and deployed by a relatively low inflation pressure. The buckling capability of a STR aluminum laminate boom is significantly improved mainly due to the high modulus of elasticity and curved cross-sectional
profile of the spring tapes. The length of a STR boom can consequently be significantly increased. It should be pointed out that spring tapes are very effective in resisting inward buckling and the aluminum laminate wall is very stable in resisting outward buckling. Therefore, these two components effectively complement each other in resisting local crippling of the boom. In addition, unlike the non-reinforced aluminum laminate booms, a STR aluminum laminate boom relies on the reinforcing tapes, not pre-strain induced by high internal pressure, to attain its post-deployment stiffness. The required inflation pressure for a STR aluminum laminate boom is relatively low. Several 5-meter long, 7.6-centimeter diameter booms have been assembled and tested. The weight of each boom is only 0.9 kilogram. The axial buckling load carrying capability of this kind of boom can reach 74 kilograms (with pin-pin boundary conditions).

Because of the unavailability of large-size membrane material, the RF aperture is assembled by seven-strips of membranes. Each membrane strip consists of 5-mil thick Kapton with 5 micrometer copper completely cover one side to serve as ground lane and many etched square patches (also 5-micrometer copper) on the other side to serve as reflectarray elements. Originally we used two-inch width double-sided adhesive tape to join two strips and the double-sided adhesive tape was covered by a four-inch width Kapton adhesive tape. However, creeps were observed along the seams one year after the assembling of the membrane. Creeps degraded the accuracy of the dimension and geometry, which can significantly impact the antenna performance.

In order to resolve the creeping problem, a new method was developed to bind the seven strips of membrane together. This method uses flexible epoxy, which made the membrane stronger with no creeping and kept the geometry intact. According to the results from the seam tests, the flexible epoxy adhesive chosen is 3M Scotch-weld two-part Epoxy adhesive (2216 B/A Gray). Adhesive is applied to the bounding area of the membrane and this area is then patched by four-inch width copper coated Kapton strip. The reason of using copper coated Kapton instead of clear Kapton is that it is easier to find adhesive to bind two metallic surfaces than to bind a metallic surface with Kapton.

c) Catenary system

A catenary system, which is composed of tensioning cord around the membrane, is used to attach the membrane to the structure and to uniformly tension the membrane, which is attached to the supporting structure by constant force springs. The whole supporting structure is only designed to hold the membrane, to stretch the membrane, to avoid wrinkles on the membrane, and to keep the flatness of the membrane.
Based on the required stress density (90 psi), the curvature of the catenary is calculated as a parabolic curve. Tubing is attached to the edges of the membrane. A string inside the tubing is used to connect the membrane to the supporting structure. The string can freely slide inside the tubing. Figure 8 shows the catenary system. The tensioning cord is pulled by constant-force springs, which are connected either to cross bars or to flat panels.

**d) Constant force springs**

The string of the catenary system is connected to 24 constant force springs (10 on cross bars and 14 on flat panels). Since a constant force spring provides a constant pulling force, the tension on the membrane does not depend on the elongation of the spring, the elongation of the springs does not have to be accurately adjusted. The use of the constant force springs is not only convenient but also necessary. When the antenna experiences substantial temperature changes in the space, the supporting structure and the membrane will expand or contract differently. Because of the constant force springs, stress distribution in the membrane will not be affected by temperature changes in the space. These springs are used to insure the stress distribution required for the membrane. Figure 9 shows how a constant force spring is attached to a flat panel.

**e) Flat panel**

Two flat panels are used at two ends of the antenna. They are made of carbon fiber material and the material has been removed as much as possible to minimize the weight. Figure 10 shows the picture of a flat panel attached by constant force springs. Flat panels are located inside the roll-up shells. Flat panels have two functions. The first one is to provide attachment points for constant force springs. The second one is to resist bending loads created by constant force springs.

**f) Roll-up shells**

Flat panels are covered by roll-up shells and figure 4 shows the roll-up shells. The carbon fiber roll-up shells have two functions. One is to provide a surface for the RF membrane to be tightly rolled up, so the thin membrane will be able to survive the launching impact. These shells also act as structural members to provide bending and compression stiffness.

**g) Cross bars**

Due to the reason that inflatable booms cannot take much bending loads, cross bars are employed as compression members to stretch the RF membrane. Each cross bar is made of carbon fiber tubing with an aluminum bracket at each end of the cross bar. Figure 11 shows how a constant force spring is installed on the aluminum bracket and connected to the cross bar. Cross bars can be rolled up onto roll-up shells with the membrane.
h) Mandrels

Mandrels have two functions. The first one is to connect inflatable booms to flat panels and roll-up shells. Figure 12 shows how a mandrel is connected to an inflatable/self-rigidizable boom and a flat panel. The second one is to provide circular surfaces for inflatable booms to roll up. It is found that the axial buckling capability of an inflatable/self-rigidizable boom after it is deployed is associated with the diameter of the mandrel while it is packaged. A mandrel is necessary to maintain the diameter of the bundle to avoid the boom damage caused by the packaging.

![Figure 12. A Mandrel Connected with an Inflatable Boom and a Flat Panel](image)

j) Launch constraining system

During the launch, the antenna has to withstand high acceleration, vibration, and acoustic impact. In order for the antenna to survive the launch, a constraining system is essential to hold the packaged antenna. The launch constraining system is composed of two half-circle lightweight shells. When these two shells are closed, the packaged antenna is constrained. After these two shells open up, the antenna can freely deploy. Figures 14 demonstrate how this launch constraining system works.

![Figures 14. Schematic of the Launch Constraining System](image)

i) End caps

End caps serve two purposes, they are used to connect the booms to the structure and keep pressure inside inflatable/self-rigidizable booms during the deployment. Each end cap is composed of outer cap, inner cap, and o-rings. Both inner cap and outer cap are machined out of aluminum. Inner cap and outer cap are pulled together by a single bolt, which causes the o-rings to expand in the radial direction and press the boom skin against the walls of the outer cap. The end caps have been tested up to 25 psi and they remained airtight. Figure 13 demonstrate how an end cap is assembled to the boom.

![Figure 13. Components of an End Cap](image)

DYNAMIC ANALYSIS

The structure of the antenna is relatively large and flimsy. The dynamic characteristics of the inflatable/self-rigidizable structure have been questioned. In order to investigate the response of the structure to the excitation introduced by the spacecraft maneuvering, a finite element model has been made and the dynamic response analysis has been conducted. The membrane itself has very little out-of-plane bending stiffness. The out-of-plane...
stiffness of the membrane is from the pretensioning. It is the function of the membrane stress distribution and is called differential stiffness. Therefore, the dynamic response analysis of a membrane structure has three steps. The first step is the static analysis to obtain the stress distribution, the second step is the modal analysis, and the third step is the response analysis.

A finite element with 568 nodes and 622 elements was assembled. The finite element software NASTRAN was used for the analysis. First of all, static analysis was performed to simulate the tensioning of the membrane and to obtain the differential stiffness. Stress distributions both in x direction (from left to right of the membrane) and y direction (from bottom to top of the membrane) were calculated and they were within the range of +1 psi of the 90 psi (90 psi is design goal). Modal analysis, incorporating differential stiffness induced by pretension of the membrane, was also performed. Figure 15 gives the first mode shape of the antenna.

After the modal analysis, transient analysis was conducted. 1% critical damping, which was reduced from dynamic test result of the inflatable/self-rigidizable boom, was used for the analysis. 0.1-G step-function disturbance (lasted for two seconds) from spacecraft attitude control was used as the excitation force. Figure 16 gives the responses of the membrane center as well as the spacecraft. It is concluded that the disturbance from spacecraft attitude control can induce displacement of up to 0.065 centimeter at the center of the membrane. 0.065 centimeter is about 0.07 of the wavelength and can cause 0.2 dB gain loss. It can also be concluded from Figure 16 that the membrane motion will decay (i.e., be damped out) to less than 0.025 centimeter (0.027 wavelength; near-zero gain loss) in 18 seconds.

DEMONSTRATION OF THE DEPLOYMENT

One of the most important tasks of this study is to use the engineering model to demonstrate the deployment process of this configuration. Figures 17 and 18 are pictures of the antenna in stowed configuration (without the launching constraining system).

When the antenna is in its deployed configuration, the membrane is stretched by constant force springs that lengthened about two inches. However, springs are not lengthened when the antenna is packaged. During the deployment, inflatable booms would have to stretch springs to their extended length before booms are fully deployed if a pre-holding system are not provided. Because the inflation pressure is very low (less than 5 psi), inflatable/self-rigidizable booms are unable to take loads before they are fully deployed. These spring loads on the booms during the deployment process prevent the success of the deployment. Therefore, a constant force spring pre-
holding system has been developed to guarantee a successful deployment.

This system is composed of two major components corresponding to two flat panels. There are two flat panels, one is stationary and another one is rotating during the deployment. The first component is a controllable string. While the antenna is in stowed configuration, all constant force springs attached to the stationary flat panel are lengthened and held by this string. As a result, these spring forces are disconnected from the membrane and inflatable booms can be deployed without any spring forces.

Every spring on the flat panel, which is rotating during the deployment, is held in position by a string attached to the locking pin. Figure 19 gives the schematic of this mechanism. The pin is placed in two brackets. The pin is pulled toward the walls of brackets by the string and is held in place by friction. When the membrane stretches the spring, the load on the pin as well as the friction force are removed. The locking pin is pulled out by a small locking spring. The locking spring has to be a soft spring so the pin cannot be self-removed when it is held in place by the friction force.

![Figure 19. Schematic of a Spring Holding Mechanism](image)

After booms are fully deployed, the controllable string attached to the stationary springs is released and spring forces are loaded on to the membrane. This causes the membrane moving toward the stationary flat panel and stretches the springs on the rotating flat panel. Consequently, locking pins on the rotating flat panel are triggered and pop out. Constant force springs on both flat panels are thus loaded directly to the membrane.

In order to have a smooth deployment, a structure was designed and built to support the antenna and eliminate some of the gravitational effects during deployment. This supporting structure is composed of two tracks and five pairs of moving arms as shown in figure 20. Every moving mandrel is attached by a roller and the roller is rotating on the track to eliminate resistance during the deployment as demonstrated by figure 21. Five pairs of arms were originally in a lower position. During the deployment, each pair of arm open up to support one of the cross bars right after that cross bar separated from the bundle. Arms are actuated by pneumatic cylinders.

![Figure 20. Deployment supporting structure](image)

Several deployment tests were successfully conducted and figures 22 show the process of the deployment, from packaged to fully deployed.

![Figure 21. Mandrel and the roller on the track](image)
FUTURE TASKS

In order to make the inflatable/self-rigidizable reflectarray antenna ready for space missions, several tasks remain to be accomplished. A few important tasks that have been planned for the near future are briefly discussed as following.

The first task is the structural thermal distortion investigation. The space thermal environment is very harsh and could distort the inflatable structure. Consequently, it could degrade the flatness of the FR membrane. Therefore, the structural thermal distortion needs to be studied. The second task is studying the effects of damping on antenna's dynamic responses to spacecraft maneuvering. The sensitivities of damping locations will be investigated and extra damping will be applied to those most effective places. The third task is performing in-space deployment dynamics analysis. Due to the gravity, deployment test of a large inflatable space structure on the Earth is very difficult and costly. Deployment dynamics analysis is therefore a necessary task for a space mission.

CONCLUSIONS

For a space mission, the launch cost is always a significant portion of the life-cycle cost. Launch cost is usually directly proportional to the launch volume and mass. Space inflatable technology is one of the emerging space technologies that can potentially revolutionize the design and applications of large space structural systems.

This paper presented the development of an inflatable structure for a three-meter Ka-band reflectarray antenna. This development took three stages. The first stage was a one-meter X-band inflatable antenna. The second stage was a three-meter (horse-shoe) Ka-band inflatable antenna. The third stage was a three-meter (movie screen) inflatable/self-rigidizable Ka-band antenna. Detailed design of the "movie screen" antenna as well as functions of each major component have been discussed. Dynamic response analysis of the antenna to the spacecraft maneuvering has been presented. The deployment test has also been exposed. The "movie screen" antenna used an inflatable/self-rigidizable technology so that any small leaks caused by material imperfection as well as micrometeoroids impact would not affect the membrane performance and inflation air is no longer needed once the antenna is inflated. Future remaining important tasks for the development of the inflatable reflectarray antenna have also been discussed.

ACKNOWLEDGEMENTS

The authors wish to thank Pierre Leung, Ubaldo Quijiano, Elvis Garay, Giovany Pelaez, and Joel Rodriguez, all of California State University at Los Angeles for their contributions to this research effort. The authors also want to acknowledge David Cadogan, Robert Lingo, John Lin, Paul McElroy, George Sharpe, Robert Wise, and other staff members of ILC Dover Inc. for their efforts on the inflatable reflectarray antennas. The work described was performed at Jet Propulsion Laboratory, California Institute of Technology under contract with the National Aeronautics and Space Administration of United States.
