Abstract

One way to measure the skill of an ocean general circulation model is to evaluate its ability to simulate observed property distributions. In this note, pressure, temperature and salinity distributions generated by a 1/6° Atlantic Ocean general circulation model are compared with climatological fields on three potential density surfaces, representative of the upper, mid-depth and deep ocean waters. The upper ocean property fields are relatively well-simulated, a testimony to the model’s ability to generally reproduce the wind-driven circulation in the North Atlantic. However, in the mid-depth and deep ocean, where wind forcing is negligible and buoyant flows associated with deep water formation play a major role in establishing property distributions, the fields are poorly represented in the 1/6° Atlantic Ocean model. The comparison between the observed and modeled fields indicates several model deficiencies in the representation of intermediate and deep waters and their pathways. Possible model improvements to reduce the mismatch between model and data are proposed.

1. Introduction

North Atlantic Ocean general circulation models have substantially improved during the last decade. Extensive model sensitivity experiments have been conducted to improve surface boundary conditions, to explore the role of horizontal resolution and to improve the choice of model parameters. Many of these studies have been conducted as part of the World Ocean Circulation Experiment's Community Modeling Effort (Bryan and Holland, 1989). The recent advent of parallel computing technology has allowed for ocean modeling at spatial resolutions of \(1/4^\circ\) (Semtner and Chervin, 1988), \(1/6^\circ\) (Smith et al., 1992; Beckmann et al., 1994; Chao et al., 1996), \(1/10^\circ\) (Smith et al., 1999), and \(1/12^\circ\) (Paiva et al., 1999). Because of the high computational costs required, these high-resolution models have been integrated for only a few decades. While this integration length is sufficient for the upper ocean to reach dynamical equilibrium, it is clearly not sufficient for thermodynamic equilibrium, particularly in the deep ocean. Thus, efforts toward the validation of these high resolution model simulations have primarily focused on features of the velocity field, such as the distribution of mean and eddy kinetic energy, the Gulf Stream separation from the western boundary, and mass and heat transports. However, the ultimate goal of ocean general circulation modeling (Semtner, 1995; McWilliams, 1995) is to reproduce not only features of the velocity field, but property field distributions as well. Understanding how properties are distributed within a basin, and eventually over the global ocean, is key to our understanding of climatic processes in the ocean. Because the distribution of a property depends largely on the integrative effects of the flow field, a model's ability to simulate observed property distributions would affirm its balance between advection and diffusion, its prescription of boundary conditions and its partitioning between mean and eddy components.

This note evaluates the property field distributions simulated by a \(1/6^\circ\) Atlantic Ocean general circulation model (Chao et al., 1996) that has been integrated for forty years. Although current computational limitations preclude the integration of this model to full thermodynamical equilibrium, it is still possible, and desirable, to compare the modeled
property fields with the climatological fields after a dynamical equilibrium has been reached (prior to 40 years) in order to address a number of fundamental questions regarding the modeled ocean circulation. These questions include:

- Are water masses being formed and spread in the model ocean?

- To what extent do the model’s water masses differ from the observed water masses in terms of gross property (temperature and salinity) strength, horizontal spread and depth of penetration?

- What is the relative location and strength of the modeled water masses?

Though we recognize that the model fields in full thermodynamical equilibrium may differ from the model fields after our 40-year integration, we believe coarse differences between the modeled and observed fields in the early stages of a thermodynamic equilibrium can signal model deficiencies in initial conditions and boundary conditions. It is important to recognize and address these model deficiencies because the use of eddy-resolving ocean circulation models for climate studies hinges on their ability to reproduce the known water mass distribution.

With the overall goal of improving the model’s thermohaline circulation, this preliminary study represents a realistic first step toward establishing thermodynamic similarities and differences between eddy-resolving ocean model simulations and observations. As part of that first step, the source of mismatches between modeled and observed fields is discussed in this work in an effort to establish a starting point for improvements in the modeled thermodynamic field. Model improvements can then be made in parallel with computational advances.
2. Data and Model

We have chosen the North Atlantic climatological hydrographic database (Hydrobase) as described by Lozier et al. (1995) for comparison with the numerical model output. Hydrobase was compiled using over eighty years of historical station data (1904-1990) from the National Oceanic Data Center (NODC). Hydrobase differs from the Levitus et al. (1994) World Ocean Atlas in that properties are averaged and smoothed on isopycnal surfaces rather than on surfaces of constant depth. As described by Lozier et al. (1994) this choice eliminates the introduction of sizable temperature and salinity anomalies into the database. Because properties are principally advected and mixed along isopycnals, our evaluation of the property fields will focus on their pattern and strength on such surfaces.

The 1/6° Atlantic Ocean model is based on the Parallel Ocean Program (POP) developed at Los Alamos National Laboratory (Dukowicz and Smith, 1994). Similar to the Modular Ocean Model (MOM, Pacanowski et al., 1991), the POP model is based on the primitive-equation formulation of Bryan (1969) and Cox (1984), but differs from it by treating sea level as a prognostic variable, i.e., it uses a free-surface rather than a rigid-lid formulation. In addition to providing a more direct means for comparison with satellite altimetric observations, the free surface POP code runs efficiently on massively parallel computers.

The Atlantic model domain covers 35°S-80°N and 100°W-20°E. This extent allows for the inclusion of deep-water formation in the Norwegian-Greenland Sea and Labrador Sea, as well as the formation of intermediate Mediterranean water in the western Mediterranean Sea. The model's horizontal resolution is approximately 1/6°, which translates into 0.1875° in longitude and 0.1843° in latitude. There are 37 levels in the vertical with 19 levels concentrated in the upper 1000 meters. The maximum grid size in the vertical is 250 meters. The model was forced by the climatological monthly wind stress and heat flux derived from the European Center for Medium-Range Weather
Forecast (ECMWF) analysis during 1983-86 (Barnier, 1995). Sea surface salinity was restored to the Levitus et al. (1994) climatology.

The model has been integrated for a total of forty years starting from a null velocity field and the Levitus et al. (1994) climatological January temperature and salinity for each level. Initial results on the model flow fields have been presented in Chao et al. (1996), Carton and Chao (1999), and Nakamura and Chao (2000). Model output during years 29-34 was used to compute the mean fields presented in this work. During this 5-year period, the volume-integrated kinetic energy per unit area (Figure 1) shows little or no secular temporal trend, suggesting that the model has established a dynamical equilibrium. The annual cycle evident in Figure 1 can be attributed to the seasonal variations of the prescribed wind stress.

[Figure 1 near here]

After a forty-year integration, however, the model has not achieved a thermodynamical equilibrium, as seen by the temporal evolution of the temperature and salinity fields at three selected depths (23 m, 1000 m, and 4000 m) (Figure 2). While the upper ocean property fields appear to be in a steady pattern, both the temperature and salinity fields in the mid-depth and deep ocean show linear trends in time. The salinity fields at mid-depth and in the deep ocean are increasing with time. Opposite trends are seen in the temperature fields: the mid-depth temperature is increasing, while the deep ocean temperature is decreasing with time. The linear trends are 0.007 and -0.001 °C/year for mid-depth and deep ocean temperatures, respectively, and 0.001 and 0.0002 psu/year for mid-depth and deep ocean salinities, respectively. These slow drifts in the mid-depth and deep ocean temperature and salinity fields are typical for decade-long integrations of this class of eddy-permitting to eddy-resolving ocean models (Haidvogel and Beckmann, 1999). Since the model was initialized with the Levitus et al. (1994) climatological January temperature and salinity values, any discrepancy between their January climatology and the model equilibrium state will cause the model’s property fields to
drift. While these drifts over 5 years are an order of magnitude smaller than the observed property variability over 80 years (Lozier et al., 1995), their cumulative effect over the years needed to reach equilibrium may be significant. Thus, our analysis of the intermediate and deep property fields will focus only on the gross characteristics of the water masses. It is important to reiterate that we recognize the equilibrium fields will differ from the fields we show in this note. However, as will be seen, it seems that discrepancies are not likely to disappear with further model integration.

[Figure 2 near here]

The mean model-simulated property fields (pressure, temperature and salinity) were projected onto three constant potential density surfaces (\(\sigma_0 = 26.50\), \(\sigma_1 = 32.35\), and \(\sigma_2 = 36.95\)), which are representative of the upper thermocline waters, lower thermocline waters and deep waters of the subtropical North Atlantic, respectively (Lozier et al., 1995). In order to facilitate the comparison with the observed fields, the model-simulated property maps, at a resolution of 1/6°, were smoothed to 1°, the nominal resolution of the observed fields. While the emphasis of this work is principally on the distribution of temperature and salinity on the isopycnals, maps of pressure will be used in this analysis to give an indication of the flow field on an isopycnal. Because the horizontal pressure gradient on an isopycnal is essentially equivalent to the slope of an isopycnal, a pressure map yields the approximate direction of the vertical shear. The horizontal pressure gradient imposed by the sea surface topography is unknown; therefore the pressure gradient deduced from the density field alone (that is, from the hydrography) yields information on the relative flow field only. If one assumes that the velocity fields goes to zero at a location in the water column (a level-of-no-motion assumption), the isobars approximate absolute flow lines. A deep level-of-no-motion for the subtropical circulation, including the Gulf Stream, its recirculation and its extension into the North Atlantic Current, is used for the interpretation of the pressure maps in this work. Thus, high pressures are to the right of the flow, looking downstream.
3. Comparison between the observed and model-simulated property fields on isopycnal surfaces

The observed and modeled pressure, potential temperature and salinity fields for the $\sigma_r=26.50$ surface are displayed in Figure 3. The model isopycnal is on average about 50-100 m deeper than the 26.50 isopycnal in the North Atlantic, yet this difference is on the order of the observed standard deviation for the pressure field (Lozier et al., 1995). The subtropical gyre is clearly displayed in both the observed and modeled pressure fields, with the gyre strength somewhat greater in the modeled field. The extent of the subtropical gyre is comparable between the model and data. As seen in the observed field, the gyre is bounded to the west and north by the Florida Current and Gulf Stream, respectively, to the east by a weak southward flow, and to the south by a broad westward return flow. Each of these limbs is reasonably well-represented by the model pressure field. The model also reproduces the westward flow of the southern limb into the Caribbean Sea, although its reentry into the subtropical basin via the Florida Straits is not well-resolved.

[Figure 3 near here]

Overall, the temperature and salinity fields on this relatively shallow isopycnal are well-represented in the modeled fields. Most striking on this density surface is the presence of a large pool of homogeneous water that fills the entirety of the subtropical basin in both the observed and modeled ocean. In the North Atlantic such homogeneity is attributed to the production of the subtropical mode water (McCartney, 1982), termed Eighteen Degree Water (Worthington, 1959), near the Gulf Stream front and its subsequent advection into the gyre interior. While the modeled water mass is slightly cooler and fresher, its overall signature represents successful production and distribution of a mode water. Likewise, the model also simulates relatively warm and salty water off the northwest coast of Africa, termed Madeira Mode Water in the North Atlantic field. Madeira Mode Water is produced from the local excess of evaporation over precipitation...
in conjunction with Ekman layer convergence (Siedler et al., 1987). Apparently, the model’s relaxation to Levitus et al. (1994) sea surface salinity suffices to generate this signature. While both of these water masses are identifiable in the modeled fields, there is a much stronger gradient between them than is observed. This difference may result from the difference in temperature and salinity of the two water masses on this surface and/or the differences in the relative strength of advection and diffusion between the ocean and model.

The intense temperature and salinity gradients that extend eastward from Cape Hatteras delineate a front between the cold, fresh waters to the north and the warm, salty waters to the south in both the observed and modeled fields. The front is considerably broader in the observed field, which may result in part from the larger temporal averaging interval for the observed fields. The model and data comparison (see Fig. 3) also reveals other model deficiencies in the upper ocean. For example, an excessively strong, quasi-permanent anticyclonic circulation near the Gulf Stream separation point is evident in the model simulation, an unrealistic feature present in several other eddy-permitting ocean models (Beckmann et al., 1994; Semtner and Chervin, 1988; Smith et al., 1992). Further downstream of the separation point, the isotherms and isoalines from the model Gulf Stream do not turn northward around the Tail of the Grand Banks. These two model deficiencies are mostly due to the lack of eddy forcing at 1/6°, and are significantly improved in the recent 1/10° (Smith et al., 1999) and 1/12° (Paiva et al., 1999) calculations. The mesoscale eddy fields, which are dynamically important for the Gulf Stream, are not fully resolved by our 1/6° model. Finally, differences are also noted in the outcrop regions for this upper surface, suggesting an investigation into how model outcrops are handled.

Figure 4 shows the observed and modeled pressure, potential temperature and salinity fields displayed on the $\sigma_1=32.35$ surface. The observed pressure field shows a strong Gulf Stream and North Atlantic extension on this surface. The signature of the subtropical gyre is noticeably absent on this isopycnal because at this depth the flow is weakly-depth
dependent (Schmitz, 1980). In contrast the isobars for the model field do not show a significant signature for the Gulf Stream nor for an extension into the North Atlantic Current. Additionally, the excessively strong meandering near the separation point is still evident at this depth. Unlike the shallower surface, this isopycnal surface, at approximately 1400 m, does not have a sharp thermal or haline front associated with the Gulf Stream and the North Atlantic Current. Instead, the warm and salty Mediterranean Sea Water (MSW) originating from the Strait of Gibraltar completely dominates the property signal in the subtropics. In the observed field the large gradients that are present in the basin interior result from the contrast of this water mass with the much colder and fresher Labrador Sea Water (LSW). One obvious deficiency in the model simulation is that the origin of the Mediterranean tongue is shifted a few degrees north of the Strait of Gibraltar. The initial field from the Levitus et al. (1994) climatology shows a tongue similar in extent and orientation to that shown in Fig. 4 for the observed field and so the realignment of the Mediterranean tongue is attributed to model dynamics and/or boundary specifications, and not to initial conditions. An examination of the model velocity field at this depth (not shown) shows a strong northward boundary current, which carries the warm and salty Mediterranean Water far to the north along the Iberian coast before spreading southeastward into the interior.

The model appears to seriously underestimate the strength of both the LSW and the MSW on this surface. The model's MSW is colder and fresher than observed, while the LSW is considerably warmer and saltier than observed. The combination of colder and fresher MSW and warmer and saltier LSW makes for weak gradients in the model basin interior. However, the cold and fresh water to the south of the Mediterranean tongue (approximately 4.0°-4.5°C and 35.00 psu), of South Atlantic origin, is well simulated in the model. We attribute this match to the fact that these waters, specified at the southern boundary, spread into the North Atlantic virtually unimpeded by topography. Apparently,
overflows (associated with MSW and LSW for example) are more problematic, as will be discussed.

The comparison on the deeper surface of $\sigma_2=36.95$, as shown in Figure 5, reveals more discrepancies between the model and data. Noticeably absent in the pressure field is a signature for the deep Gulf Stream and its associated recirculation that are seen in the hydrographic data (Lozier, 1997). Unlike the observed fields, the model flow field shows a significant southeastward flow of water extending from the high latitudes into the subtropical basin. Thus, the southwestward flow centered at 30°N is associated with this flow of northern waters and not the recirculating deep Gulf Stream waters, as observed in Fig. 5.

[Figure 5 near here]

The temperature fields on this deep isopycnal differ sharply. Although the model does show a tongue of warm and salty water emanating from the Mediterranean outflow region, as with the previously discussed surface, its origin is more northward than observed. Additionally, the axis of the model advective and diffusive tongue is shifted to the south from the observed axis. The MSW is again cooler and fresher than observed and the high latitude waters are warmer and fresher. As a result, the gradient field on this surface is also significantly different in the observed and modeled field. For instance, in the western basin the modeled isotherms are nearly orthogonal to the observed ones. The difference in these deep temperature fields suggests that North Atlantic Deep Water (NADW), along with MSW and LSW, are not properly simulated in the model.

4. Meridional Section of Salinity

The water mass structure of the North Atlantic can also be viewed with a meridional section of salinity (Tsuchiya et al., 1992; Tsuchiya et al., 1994; Talley, 1996). Figure 6 shows a latitude-depth section of annual-mean salinity averaged between 30°W and
20°W, for both the observed (a) and the modeled (b) ocean. Our comparison for this section uses the Levitus et al. (1994) climatology since we wish to make the comparison over the whole model domain, which reaches to 35°S. The effect of the “closed” southern boundary at 35°S is clearly evident. Within the buffer zone between 30°S-35°S, the modeled salinity is almost identical to the observed value, because of the strong restoring to the Levitus et al. (1994) climatology at all levels. The difference between the observed and modeled salinity fields contributes to the sharp gradient between the model interior and the buffer zone at about 30°S. This boundary problem becomes less apparent below 500 m.

The major water masses, which contribute to the North Atlantic Ocean circulation, are evident in the observed field as shown in Fig. 6a. The northward inflow through the model’s southern boundary at 35°S is evident from two low-salinity features: the Antarctic Intermediate Water (AAIW) centered on 900 m, and the Antarctic Bottom Water (AABW) below 4000 m. Sandwiched between these two water masses of the southern origin is the relatively salty NADW, which lies between 1500 and 4000 m. The northward tongue of AAIW penetrates to approximately 20°N, while AABW penetrates further northward, to the edge of the section at about 40°N. The saline MSW signature lies between 30°N-40°N and is centered at about 1000 m. Finally, around 45°N-60°N and between 1500 and 3000 m, a pool of low-salinity LSW is found.

A comparison of the model section (Fig. 6b) with the observed section (Fig. 6a) shows that the near-surface salinity is relatively well-simulated, with high salinity waters in the subtropical North and South Atlantic and low salinity waters in the northern North Atlantic. This is not surprising since the model surface salinity is restored toward the climatological values (Levitus et al., 1994). However, the modeled salinities in the subtropical North and South Atlantic are still fresher (by 0.3 psu) than the observed, and the modeled salinity in the northern North Atlantic is saltier (by 0.2 psu) than the observed. Also, because of the restoring boundary condition near the southern boundary,
the model realistically simulates the AAIW. This modeled water mass lies between 500 m and 1500 m, and extends from the southern model boundary to about 15°N.

The modeled MSW, on the other hand, is significantly shallower and occupies a much broader region in the model than is observed. Additionally, the pool of LSW in the northern domain is virtually absent in the model. The NADW penetrates southward only to the equator in the modeled ocean. The modeled AABW, seen as a northward tongue of relatively fresh deep water, is centered at about 4000 m, significantly shallower than the observed AABW. In fact, over much of the North Atlantic basin, the AABW overrides a portion of the NADW, such that the bottom water is composed of NADW, rather than AABW, as observed.

[Figure 6 near here]

In sum, the water masses, which fill the North Atlantic basin, are identifiable in the model, however, their strength, horizontal penetration and vertical extent differ substantially from the observed fields. The source of these differences will be discussed in the next section.

5. Discussion and Summary

Overall, the upper ocean property fields are relatively well-simulated, yet the mid-depth and deep ocean property fields are poorly represented in the 1/6° Atlantic Ocean model that has been integrated to forty years. A representative simulation of an observed property field hinges on many aspects of the model, including adequate boundary conditions and the correct balance between advection and diffusion and between mean and eddy components. Our evaluation of the modeled property fields points out two possible problems in the model: (1) improper boundary specifications of water masses; and (2) inadequate treatments of bottom boundary layer processes. Each of these will be discussed in turn.
The "closed" model boundary is approximated by the buffer zone (or sponge layer) where the model temperature and salinity are restored toward the Levitus et al. (1994) climatology. It is known that the Levitus et al. (1994) climatology was obtained by applying heavy averaging along isobaric surfaces. Such averaging, by essentially mixing surrounding waters with the "boundary waters", could produce the observed dilution of the model's NADW, LSW and MSW. It would be desirable to specify the boundary conditions using Hydrobase (Lozier et al., 1995). Hydrobase is gridded on isopycnal surfaces with smaller averaging scales and has the advantage that it preserves the original temperature-salinity characteristics of the raw hydrographic data. Thus, before one can assess whether the model does an adequate job distributing the water mass from its origin, it is essential to adequately represent the water masses at their point of entry into the model domain.

Another major problem in the model is the poor model representation of bottom boundary layer processes (e.g., flow over topography). The staircase representation of the bottom topography used in z-coordinate ocean models (e.g., MOM and POP) tends to diffuse the property fields, thus preventing the deep water from reaching the deep ocean. For example, the poor representation of the overflow processes through the Denmark Straits west of Iceland, the Iceland-Faroe Ridge east of Iceland, and the Faroe-Shetland Channel farther to the east contribute to mismatches between the modeled and observed fields. During the past few years, there have been several bottom boundary layer schemes (Beckmann and Döscher, 1997; Gnanadesikan et al., 1999; Killworth and Edwards, 1999; Döscher and Beckmann, 2000; Song and Chao, 2000) designed to improve the topographic representation in z-coordinate ocean models. Our preliminary results with an idealized test problem have shown that the embedded bottom boundary layer formulation developed by Song and Chao (2000) is quite effective in moving the NADW to the deep interior ocean. It is expected that the implementation of this bottom boundary layer scheme in the 1/6° Atlantic model will significantly improve the property field simulations in both the overflow region and the model interior.
In addition to evaluating property field simulations with our improved specifications of water masses and bottom boundary layer parameterizations, it is important to perform the type of data and model comparisons as presented in this note with other eddy-permitting to eddy-resolving simulations (e.g., Smith et al., 1999). Given the limited computing resources available for these high-resolution simulations (Semtner, 1995), it would be cost effective to implement the measures necessary to improve property field representations before increasing the horizontal resolution even further. Ultimately, improved property field simulations will lead to improved simulations of the flow field, particularly in the deep ocean.

Acknowledgments. The research described in this publication was carried out, in part, at the Jet Propulsion Laboratory (JPL), California Institute of Technology, under a contract with the National Aeronautics and Space Administration (NASA). Computations were performed on the Cray T3D computer through the JPL Supercomputing project. MSL gratefully acknowledges the support of the NASA, via a subcontract from JPL.
