ABSTRACT

We present the $V$ and $J$ light curves of a nova discovered in the disk of the spiral galaxy M100, located in the Virgo cluster. In spite of the fact that the light curve is not well-sampled around maximum light and the reddening to the nova is not accurately known, by adopting the maximum magnitude versus rate of decline relation by Della Valle and Livio (1995, ApJ, 452, 704) we derive a distance modulus to M100 $\mu_0 \sim 31.04 \pm 0.3$, fully consistent with the Cepheid distance modulus of $31.04 \pm 0.17$ mag found by Ferrarese et al. (1996, ApJ, in press) from the same set of HST/WFPC2 data.

Subject headings: Novae, cataclysmic variables - stars: distances galaxies: individual (M100, NGC 4321)
1. Introduction

The aim of the Hubble Space Telescope (11 ST') Key Project on the Extragalactic Distance Scale [e.g. Freedman et al. (1994a), Freedman et al. (1994b), Freedman et al. (1994c), Mould et al. (1995), Kennicutt et al. (1995)] is to refine the zero points of secondary distance indicators by measuring Cepheid distances to a sample of 18 galaxies, out to distances of about 20 Mpc. These galaxies are located in the field, small groups (e.g. Leo I) and larger clusters (Virgo and Fornax). In addition to Cepheids, several other variable stars are bound to be discovered, even if the observing strategy is not designed to provide the best sampled light curve and/or period determination. Possible detections are eclipsing binaries, short-period variables such as RRLyrae stars, Luminous Blue Variables — and novae. Even if a systematic search for any of these variables has not been carried out in any of the Project's galaxies (after all, Cepheids are the primary objective), occasionally some of them are in fact observed [Freedman et al. (1994a), Kelson et al. (1996), Silbermann et al. (1996), Ferrarese et al. (1996)]. In particular, we report in the present work the detection of a nova in the spiral galaxy M100, located in the Virgo cluster. This is a truly exciting discovery: only a handful of novae have been observed as far as Virgo [two are reported by Hubble (Bowen (1952)) in M87, nine more in an immense effort by Pritchett and van den Bergh (1987) in NGC 4472 and NGC 4365].

The M 100 nova surpasses all of the previous discoveries in terms of the sampling of the light curve and the quality of the photometry, in spite of the fact that the usefulness of one nova in M 00 as a distance indicator is limited (at best), especially when a more solid distance to the same galaxy is available through a sample of a few dozen Cepheids, this nova is a precious addition to the sample of novae already known in the Galaxy, LMC, M31, M33, NGC 5128, M81 and Virgo. Its excellently determined light curve testifies to the case with which 11 ST' can find such objects and to their potential use as distance
indicators in remote galaxies. Furthermore, a comparison with the Cepheid distance allows an assessment of the quality of the maximum magnitude versus rate of decline (MMRD) relation for novae. After the discovery of the M1 00 nova, the photometry for all of the Key Project galaxies is currently being re-examined in a search for novae.

In this short letter, we therefore report the discovery of the M100 nova, present its V and J light curves, and apply it to the MMRD relation. We also discuss briefly the nova rate in M1 00.

2. Observations

The set of observations that led to the detection of the M100 nova are presented in detail and extensively discussed in Ferrarese et al. (1996) and Hill et al. (1996). In those papers, the reader can also find details of the reduction procedure and the photometric analysis. Here it suffices to say that the nova was observed in twelve V (F555W) and four J (F814W) epochs using the Wide Field and Planetary Camera 2 on board HST. The observations span a period of 58 days. Unfortunately, the nova outburst occurred between the first and the second epoch, which are set about 11 days apart, and we therefore lack good sampling of the light curve near maximum light.

3. Results and Discussion

Plate 1 shows a gray scale group-based image of M100, obtained by R. Peletier with the Isaac Newton Telescope at La Palma. We have superimposed a deep HST/WFPC2 exposure obtained by combining all twelve V epochs. The nova, shown by the white circle, was found in an uncrowded region in the outer part of the galactic disk. The low stellar density in the region around the nova is better seen in Plate 2, which shows a 22" x 22"
region centered on the nova itself, as it appears in the first (before outburst), second, sixth and last epochs. The dramatic change in the brightness of the nova between subsequent epochs is readily apparent. The absence of nearby companions and bright stars makes it very easy to obtain extremely accurate photometry in this region, as testified by the very low errors associated with the nova magnitudes (Table 1).

The V and J light curves of the M1 00 nova are shown in Figure 1 and tabulated in Table 1. Although we are missing data around maximum light, the declining part of the light curve is beautifully sampled. We believe this to be an important result on its own account: since well sampled (high accuracy) nova light curves are rare in the literature, the M 100 nova provides a useful template for novae with similar decline rates. The nova light curve, linear in the earliest part of the decline and then sloping more gently at later times, is typical of very well sampled novae found in the literature (e.g. Nova Cyg 1975 and nova Cyg 1978, vandenBergh anti Younger (1987)); we note that the almost linear decline shown by some novae (e.g. Rosino (1973), Arp (1956), vandenBergh and Younger (1987)) is most likely the result of poor temporal sampling rather than being intrinsic.

An accurate distance to M100 was determined as a part of the HST Key Project on the Extragalactic Distance Scale, by fitting Period-Luminosity relations to a sample of 52 Cepheids found from the same set of HST/WFPC2 data in which the nova was discovered (Ferrarese et al. (1996)). The M1 00 Cepheid distance modulus is \( \mu_0 = 31.043 \pm 0.1 \) 7 mag, and the total (Galactic plus internal) mean color excess \( E(B-V) = 0.10 \pm 0.06 \) mag.

The usefulness of novae as distance indicators relies on the existence of a relation between the absolute magnitude at maximum light and the rate of decline, also known as the MMRD relation. In this paper we adopt the formulation of the MMRD relation obtained by Della Valle and Livio (1995). While it is not possible to obtain a reliable distance to M1 00 based on one nova, it is useful to estimate a distance on the basis of the
MMRD relation, as a consistency check.

There are two main sources of uncertainties in deriving a distance to M100 from the nova light curve: the V magnitude at maximum light, and the reddening. The reddening for the nova is likely lower than for the M100 Cepheids \( E(B-V) = 0.10 \pm 0.06 \text{ mag} \) \cite{Ferrarese1996}, since Cepheids are found in regions of more recent star-forming activity and more dust. On the other hand, the reddening of the nova cannot be lower than provided by the Galactic foreground extinction: \( E(B-V) = 0.01 \pm 0.015 \text{ mag} \) \cite{Burstein1984}. In all cases, following Ferrarese et al. (1996), we will assume \( A_V/E(B-V) = 3.3 \), the standard value for the interstellar medium, and adopt the reddening law by Cardelli, Clayton, and Mathis (1989).

An upper limit to the distance can be easily determined: adopting the lower limit for the reddening (since we are deriving an upper limit to the distance, \( E(B-V) = 0.01 \pm 0.015 \text{ mag} \)), we can confidently say that \( m_{\text{max}} \leq 23.963 \pm 0.04 \text{ mag} \) (equal to the magnitude, corrected for extinction, at the second epoch). Counting from this magnitude, the time taken by the nova to decline by two magnitudes is \( t_2 \sim 19 \text{ days} \) which, when substituted into the Della Valle and Livio (1995) MMRD relation, gives \( M_V \sim -8.1 \text{ mag} \). The corresponding distance modulus then must be \( \mu_0 \leq 32.1 \text{ mag} \).

On the other hand, a lower limit to the distance can be obtained assuming that the light curve has zero rise-time (i.e. the maximum is reached at the first epoch), and a "sawtooth" shape (i.e. the decline is linear): Livio (1992) shows that nova light curves in the early phase of the decline are indeed approximately linear, with a slope equal to \( 2/t_2 \). Since we are calculating a lower limit to the distance, we adopt the upper limit on the reddening \( (E(B-V) = 0.103 \pm 0.06 \text{ mag}) \). By fitting a straight line to the first three points (after maximum) in our light curve we obtain \( t_2 = 11 \text{ days} \) \( (t_2 = 13 \text{ days} \) if the first four points are used). From the Della Valle and Livio (1995) MMRD relation, \( M_V = -8.6 \). According
to our assumptions, the apparent magnitude at maximum must be fainter than the $M_V$ intercept of the straight line at the time corresponding to the first epoch (II) = 2449465.78, $m_V > 22.1$ mag. From this, we obtain $\mu_0 \geq 30.7$ mag.

A more precise estimate of the distance modulus can be attempted by knowing that at maximum light $(B - V)_0^{\text{max}} = -0.234 \pm 0.00$ [van den Bergh and Younger (1987)]. This implies that the nova progenitor is of spectral type between A7 and F0, therefore the $B - V$ color translates to $(V - I)_0^{\text{max}} \sim 0.37 \pm 0.10$ [e.g. Zombeck (1990)]. According to the arguments presented earlier in this section, we constrain the reddening to be $E(B - V) = 0.06 \pm 0.03$ mag (where the error represents the standard deviation assuming a uniform probability distribution over the range $0.01 \leq E(B - V) \leq 0.10$). If the $V$ and $I$ light curves are fit with an exponential profile (the best fits are shown in Figure 1) the condition $(V - I)_0^{\text{max}}$ is satisfied for $V \sim 22.27 \pm 0.11$ mag, implying $t_2 \sim 8.4 \pm 0.7$ days, $M_V \sim -8.77 \pm 0.04$, and $\mu_0 \sim 31.04 \pm 0.2$. To this formal error, we need to add (in quadrature) the uncertainty due to the intrinsic scatter observed around the MMRD relation, corresponding to $\sigma \sim 0.2$ mag [e.g. Della Valle ant Livio (1995)]. This brings the uncertainty on the distance up to 0.3 magnitudes. However, the reader should not be misled by the still apparently small error bar: it does not take into account deviations, undoubtedly present, of the real light curve from our adopted exponential fit. The derived distance falls just in the middle of the acceptable distance range derived in the previous paragraph and it agrees remarkably well with the Cepheid distance derived by Ferrarrese et al. (1996). Good agreement is also present between the M100 distance derived in this paper and the distance to Virgo cluster elliptical galaxies derived by Pritchet and van den Bergh (1987) from observations of six novae ($\mu_0 \sim 31.454 \pm 0.43$).

We conclude this letter with a short note on the nova rate. Della Valle and Livio (1994) found an approximately linear relationship between the rate of production of novae and the $M_{I}$ luminosity of the parent galaxy. This relationship, applied to M100 [$m_{I} = 8.97$
mag, Aaronson (1977) predicts that about 15 novae/year are expected in the galaxy. An empirical estimate of the nova rate in M 100 is easily derived. The WFPC2 field of view, which is $\sim 5.7$ arcsec squared, covers about $1/4$ of the stellar flux of the entire galaxy. Having observed one nova in a 58-day window, the nova rate per year is about 25, in agreement with the Della Valle and Livio (1994) prediction.

We are indebted to Dr. John Graham for the many suggestions and comments. We wish to thank lb.- R. Peletier who kindly made available the ground-based image of M 100 shown in Plate 1. Support for this work was provided by NASA through grant number 2227-87A from the Space Telescope Science Institute which is operated by the Association of Universities for Research in Astronomy inc. under NASA Contract, NAS5-26555. MI acknowledges support from NASA Grant NAGW-2678 at the Space Telescope Science Institute.
