Abstract. We analyze the new mid-infrared maps of NGC 6946 for variations in the color ratio of the 7-to-15 µm emission. Our preliminary findings are that this mid-infrared color is remarkably constant between arms and inter-arm regions, and as a function of radius in the disk, excluding the nuclear region. As surface brightness ranges by more than an order of magnitude and the radius runs from about 0.5 to 3 kpc, the color ratio remains constant to about 20%. Our interpretation is that (1) mid-infrared colors are not particularly sensitive to the variations of the heating spectrum between star-forming regions and diffuse heating regions; and (2) that surface brightness variations are driven primarily by surface-filling fraction in the disk, and try radiation intensity increases in starburst environments, such as the nucleus of NGC 6946.

Keywords: Infrared - Galaxies; Galaxies -- individual; Galaxies - ISM

1. Introduction

"Jim Infrared Space Observatory (ISO; Kessler et al. 1996) provides a unique opportunity for extending the study of star formation to systems that have remained inaccessible to suborbital platforms in infrared (IR) spectroscopy and low-brightness imaging. The "ISO Key Project" on the interstellar medium of normal galaxies, which is part of the NASA Guaranteed Time, uses ISO to derive the physical properties of the interstellar gas, dust and radiation field in a broad sample of "normal" disk galaxies, defined as systems whose luminosity is dominated by star formation. The project collects a variety of diagnostics from ISO instruments, mainly ionic and atomic fine-structure line fluxes using IWS (Clegg et al. 1996), far-IR continuum fluxes and mid-IR spectra using PHOT-C and I10'J-S (Lenke et al. 1996), and mid-IR maps at 7 and 15 µm using CAM (C. Cesarsky et al. 1996). Two groups of objects are included: About six nearby galaxies such as NGC 6946 provide spatially resolved cases where the various phases of the interstellar medium (ISM) can be studied separately, and their signatures in each observable identified. About sixty distant galaxies with small apparent IR sizes were selected to span the full range of morphology, luminosity, IR-to-blue ratio, and IRAS colors that are covered by star-forming galaxies. By characterizing the variation in ISM properties in this diverse sample, we hope to gain new insight into the star formation process on the scale of galaxies, especially its drivers and inhibitors.

We report in this paper on analysis of the first data obtained for the KeyProject on normal galaxies, namely ISO-CAM maps at 7 and 15 µm of NGC 6946, aimed at understanding the mid-IR colors and their variation within the disk of this spiral galaxy (Malhotra et al. 1996). IR colors formed among the IRAS bands are well known as sensitive indices of the radiation intensity in the ISM of galaxies (Soifer, Houck & Neugebauer 1987; Helou & Wang 1996).
IRAS data established that mid-IR (5 \( \leq \lambda \leq 40\mu m \)) emission from the ISM and star-forming galaxies is dominated by fluctuating grains and Polycyclic Aromatic Hydrocarbons (PAH) whereas classical grains in thermal equilibrium dominate at longer wavelengths (Helou 1986). Many questions however remain about the precise nature of the PAH (Puget & Léger 1989), their life cycle and excitation conditions, some of which we address by a detailed study of the mid-IR colors of galaxies.

Early results from ISO already show the 7\(\mu \)m filter of CAM (LW2, \(\lambda \lambda \leq 3.5\mu m\)) to be primarily sensitive to major PAH emission features at 6.3 and 7.7\(\mu m\), whereas the 15\(\mu m\) filter (LW3, \(\lambda \lambda = 6\mu m\)) picks up emission from a minor feature at 12.6\(\mu m\), but mostly from any continuum due to fluctuating very small grains at wavelengths out to ~18\(\mu m\) (Vigny et al. 1996; D. Cesarsky et al. 1996). The 7- to 15\(\mu m\) ratio should thus measure a feature to continuum ratio, and might be expected to gate the PAH to small grain ratio.

2. Observations and Data reduction

NGC 6946 was mapped at 7\(\mu m\) (LW2 filter, \(\lambda \lambda \leq 3.5\mu m\)) and at 15\(\mu m\) (LW3 filter, \(\lambda \lambda = 6\mu m\)), using the raster scanmode to cover roughly 12.5' x 12.5' centered on the nucleus. CAM was set to 6''/pixel, and the raster was made up of 8 x 8 points separated by 81'', or 135 pixels, in each direction for better spatial sampling. The details of data reduction and image reconstruction are given in the companion paper by Malhotra et al. (1996). These maps are based on a preliminary data reduction and overall calibration with a 30\% uncertainty, so we will not address here the absolute value of the color ratios.

The images resulting from this preliminary data reduction were constructed on a grid with 3'' x 3'' pixels, and achieved a spatial resolution of a FWHM of 7.2'' at both wavelengths. The noise levels in these images are approximately 0.1 M\(\mu\)Jy sr\(^{-1}\) at 15\(\mu m\) (J;arcsec\(^{-2}\) for comparison, the clean images in the IRAS Sky Survey Atlas (Wesselock et al. 1994) reach a noise level about three times lower at 12\(\mu m\) in a 4'' beam, i.e. a solid angle 1600 times greater than the ISO-CAM images. Features roughly a thousand times brighter than the noise are still reliably measured in these maps. The inner 15'' or so are too bright to measure, and the surface brightness at the nucleus exceeds 300 and 560 M\(\mu\)Jy sr\(^{-1}\) respectively at 7 and 15\(\mu m\).

Any estimation of the color of the galaxy, especially in the outer regions of the galaxy, is strongly affected by the subtraction of the zodiacal light. The zodiacal foreground was determined from an annulus of radius 5' centered on the nucleus of NGC 6946 after deprojection of the map assuming an inclination angle of 30° and a position angle of 67°. At 7\(\mu m\) the zodiacal surface brightness equals the galaxy's surface brightness at the radius of 2', and is ~ 80 times the noise level in the final map. In addition, spatial gain variations in the maps affect significantly the color estimates, since the zodiacal light and galaxy have very different mid-IR colors, with the latter showing a 7- to 15\(\mu m\) ratio 4 to 5 times greater.

3. Color Gradient in the Disk

The ISO-CAM maps of NGC 6946 have enough resolution, sensitivity and extent to allow a characterization of the mid-IR color behavior as a function of position in the disk. Mid-IR morphology at both 7 and 15\(\mu m\) is generally similar to optical, radio and H\(\alpha\) images, with an exponential disk well defined through flocculent arms (Malhotra et al. 1996). Diffuse emission from the disk in the interarm regions is clearly detected and can be traced out to ~5'. The disk is relatively symmetric, making it unlikely to be the result of transient effects in detectors or other artifacts. However, a simple color map of the 7 to 15\(\mu m\) images shows essentially no sign of structure, suggesting that the colors are relatively constant across all these morphological elements.

In their analysis of scale lengths, Malhotra et al. (1996) show the radial profile of the disk defined by the median brightness at each radius to be indistinguishable between the two CAM maps at 7 and 15\(\mu m\). This is compelling evidence for the absence of any radial gradient in the "mean" mid-IR color versus the median brightness drops by a factor of ~10.

4. Arm-Interarm Color Contrast

In order to address the question of color variation between arm and interarm, we introduce a relatively objective definition of physically similar and contiguous regions based on brightness. We first deproject the galaxy assuming an inclination angle of 30° and a position angle of 67°. We then consider the distribution of surface brightness in all pixels within an annulus 15'' wide, and take the arms to be those pixels that were the top-ranked 25% in both the 7\(\mu m\) and 15\(\mu m\) maps. Similarly, the lowest-ranked 25% of pixels are taken to be the diffuse disk or interarm regions. The result of that sorting is shown in Figure 1, which demonstrates that the method identifies reasonably well arms that would be picked out by eye. The transition region around the median of the distribution is not considered in the following discussion. The two map condition on the brightness selection is necessary to avoid biasing the color ratio by selecting pixels that are a priori high in either the numerator or denominator.

The colors are then estimated as the ratio of the integrated surface brightness between 7 and 15\(\mu m\) in the arm and interarm region in each 15'' annulus. The run of 7- to 15\(\mu m\) colors is plotted against radius in Figure 2, and against surface brightness in Figure 3. The uncertainty bars shown reflect two extremes of possible errors, namely that the zero point subtraction is off by one of opposite directions for each of the numerator and denominator in
the color ratio, where \( \sigma \) is the noise in the empty part of the map, \( \sim 0.1 \) MJy sr\(^{-1} \). This is clearly a conservative estimate of the possible error in the zero-point determination.

![Fig. 1. Selection map showing the areas assigned to arm and inter-arm by the mid-IR brightness sorting method described in §3. The darker areas correspond to arms, whereas the lightly shaded areas correspond to diffuse disk or inter-arm regions, and blank areas to the transition regions which are not considered further here.](image1)

Fig. 1. Selection map showing the areas assigned to arm and inter-arm by the mid-IR brightness sorting method described in §3. The darker areas correspond to arms, whereas the lightly shaded areas correspond to diffuse disk or inter-arm regions, and blank areas to the transition regions which are not considered further here.

It is clear from Figure 2 that the mid-IR colors are generally quite constant across the disk. There is a slight trend for an increase in the 7-to-15\( \mu \)m ratio with increasing radius, but this trend is not significant in view of the uncertainties assumed. This analysis complements the results discussed in §3, since those results pertain to the median brightness whereas these plots address the upper and lower quartiles in the brightness distribution. We conclude that the 7-to-15\( \mu \)m color is constant to within \( \pm 20\% \) in the disk of NGC 6946. This conclusion applies whether one compares arms and diffuse disk, or whether one considers the brighter, medium or dimmer parts of the disk as a function of radius.

In the innermost three annuli plotted in Figure 1, arms and inter-arm regions show slightly different colors, a difference on the order of 2\( \sigma \) only. Given the preliminary status of the data reduction we take a cautious view of the reality of this difference, especially that the detectors would be most susceptible to systematic problems here because of the very bright nuclear region.

Figure 3 shows no systematic dependence of color on surface brightness, which would have been a direct indication of errors in the zodiacal foreground subtraction or of non-linearities in the flux-scale calibration of either one of the two CAM maps. It again illustrates the basic constancy of color as the surface brightness ranges by a factor of 20. Interestingly, the color difference hinted at in Figure 2 becomes more significant in Figure 3 as one compares points with similar surface brightness, as it appears just where the brightest inter-arm regions and the dimmest arm segments have comparable brightness.

The CAM data are consistent with the 7-to-15\( \mu \)m color dropping further as one approaches the nucleus, but are not sufficiently reliable to draw firm conclusions (Malhotra et al. 1996). Sue) a change in color however would be consistent with the data in the Antennae galaxies (Vigroux et al. 1996), where the 7-to-15\( \mu \)m ratio drops by a factor of 2 in the very bright “interaction region” where a star-burst is in progress just as one is known to be occurring in the nucleus of NGC 6946.

![Fig. 2. Variation of the 7-to-15\( \mu \)m color ratio as a function of radius for each of the arms and inter-arm regions. Note that both here and in Figure 3 we have excluded the nuclear region where the galaxy's brightness exceeds the linearity range of the detector. The uncertainty bars for the colors in the arms are shown as solid lines, and those in the inter-arm regions as broken lines.](image2)

Fig. 2. Variation of the 7-to-15\( \mu \)m color ratio as a function of radius for each of the arms and inter-arm regions. Note that both here and in Figure 3 we have excluded the nuclear region where the galaxy's brightness exceeds the linearity range of the detector. The uncertainty bars for the colors in the arms are shown as solid lines, and those in the inter-arm regions as broken lines.

5. Discussion

The constancy of mid-IR color across the disk and against variations in the surface brightness is somewhat surprising, since one would expect the heating spectrum to change substantially between arm and inter-arm regions, as the former contains more \( \text{HII} \) regions, massive stars, and therefore a heating spectrum richer in UV photons. The lack of variations suggests that the emission spectrum between 5 and 18\( \mu \)m is not particularly sensitive to the
Density of distinct and independent star forming regions, each of which emits a similar spectrum in the mid-IR. As star-burst conditions are reached however, the density of 1111 regions increases to the point of superposition and the heating intensity increases dramatically, causing the surface brightness to increase by at least another order of magnitude.

This analysis leads us to predict that most galaxies will display 7- to 15μm colors similar to the ones observed in NGC 6946, with any exceptions signalling star-burst conditions, meaning extremely high heating intensities and UV-rich heating spectra. Spatially unresolved galaxies with both normal and star-burst components will of course display intermediate mid-IR colors.
