TEST-DERIVED EFFECTIVE EMITTANCE FOR CASSINI MLI BLANKETS AND HEAT CHARACTERISTICS IN THE VICINITY OF SEAMS

Edward I. Lin*, James W. Stultz* and Ronald T. Reeve†
Jet Propulsion Laboratory
California Institute of Technology
Pasadena, California

Abstract

Thermal performance of Cassini MLI blankets was characterized in thermal vacuum tests. Effective emittance was derived for the standard and high-temperature layups, with or without micrometeoroid protection standoffs, and for a high-performance duo-layup with staggered seams. The all-Kapton layup was shown to have a 19% higher effective emittance than the hybrid Kapton-Mylar layup, and the duo-layup exhibited a dramatic capability of reducing heat dissipation by 2.6 fold. Several different definitions of effective emittance are discussed, and their relations to distinct hardware-MLI configurations and corresponding modeling techniques clarified. Large temperature differences (up to 70°C) were observed between the center and scam of a blanket. Heat losses in the vicinity of seams are quantified, and a major MLI heat loss mechanism elucidated.

The Cassini spacecraft is being developed for a mission to explore Saturn and its rings, satellites and magnetosphere. The scheduled 1997 launch will take the spacecraft through a Venus-Venus-Earth-Jupiter Gravity Assist (VVEJGA) trajectory, subjecting it to a 0.61 AU (Astronomical Unit) high-temperature environment at perihelion. Temperatures on some sunlit blanket surfaces at 0.61 AU can reach levels that are beyond the service capability of the conventional Mylar/Dacron net MLI. For example, the Radioisotope Thermoelectric Generator (RTG) shade MLI temperature is predicted to be around 300°C under the combined heating of the RTG (3900 W) and 2.7 suns (i.e., at 0.61 AU) during a trajectory correction maneuver. The main engine blanket tempature can reach 360°C during engine firing in conjunction with the 0.61 AU solar illumination. The majority of the blanket surfaces, however, will experience temperatures with an upper bound of 250°C, since the spacecraft will cruise in the shade of its high gain antenna which is sun-pointed most of the time.

These worst-case hot Cassini MLI temperature prediction are significantly higher than those expected for previous spacecraft, e.g., the Galileo. To cope with the
high temperature environment, the baseline Cassini ML1 design includes a “standard layup” and a “high temperature layup”. The high temperature layup consists of 20 layers of embossed Kapton with a black Kapton outerlayer, and will be used only at locations of extremely high temperatures, such as in the vicinity of the RTG and the main engine. The standard layup is a hybrid consisting of 5 layers of embossed Kapton and 15 layers of Mylar/Dacron net with appropriate outer and inner layers, and will be used at over 85% of the blanketed surfaces cm the spacecraft.

The high temperature survivability of these layups has been successfully demonstrated in a series of high-temperature exposure tests which employed a 2.7-sun solar simulator. However, the thermal performance of these layups, specifically their effective emittance in several hardware configurations, has not been characterized before. For example, while experience and intuition suggested that the all-Kapton layup would be “leakier” (i.e., have higher effective emittance) than the conventional Mylar/Dacron net type construction because of greater inter-layer contact and greater susceptibility to local compression, no effective emittance data existed to provide a convincing comparison. In addition, due to micrometeoroid protection requirements, ML1 blankets at numerous locations are spaced off the hardware by 3.81 cm or 6.35 cm with Mylar standoffs. Elsewhere, they are either closely wrapping around the hardware, or are installed in a tent-like configuration. It has been found that the manner of blanket installation significantly determines the method of modeling which in turn invokes the appropriate definition of ML1 effective emittance, This was not previously discussed in the literature, yet this has important consequence in terms of the values to be used for the effective emittance, as well as the temperatures which result from the analysis.

This paper will start by presenting some fundamental considerations related to various definitions of ML1 effective emittance, and the associated techniques of thermal modeling. A description of the test articles, setup and procedure will then follow. The test results will be analyzed yielding effective emittance data applicable in various situations. As a bonus from the test program, the heat loss characteristics in the vicinity of blanket seam will be discussed. Finally, a method of fabricating high-performance ML1 blanket will be validated, complete with quantitative performance characterization.

Effective Emittance - Basic Considerations

The effective emittance of an ML1 blanket is mathematically defined as:

\[ \epsilon_{\text{eff}} = \frac{Q}{A \int (T_H - T_C)} \]  

Several interpretations of this equation are possible depending on what \( T_H \) and \( T_C \) are taken to be. This is directly related to how the analyst models the hardware, and it determines what value the analyst should use for the ML1 effective emittance. This is not always clear in thermal analysis and the reporting of effective emittance in the literature usually does not make any distinction among the various interpretations. Thus significant errors sometimes result. The following three definitions of \( \epsilon_{\text{eff}} \) are encountered in the Cassini thermal design, each relevant to a particular hardware-blanket configuration.

\[ \epsilon_{\text{eff}} = \epsilon_{\text{eff, hr}} \quad \text{if } A = A_{\text{hardware}}, \quad T_H = T_{\text{hardware}}, \quad \text{and } T_C = T_{\text{outer-layer}} \]  

\[ \epsilon_{\text{eff}} = \epsilon_{\text{eff, ho}} \quad \text{if } A = A_{\text{ML1}}, \quad T_H = T_{\text{ML1}}, \quad \text{and } T_C = T_{\text{outer-layer}} \]  

\[ \epsilon_{\text{eff}} = \epsilon_{\text{eff, ho}} \quad \text{if } A = A_{\text{ML1}}, \quad T_H = T_{\text{inner-layer}}, \quad \text{and } T_C = T_{\text{outer-layer}} \]  

Figure 1 illustrates the three hardware-ML1 configurations that call for modeling techniques invoking the above three definitions for effective emittance. Configuration (a) involves wrapping the ML1 blanket snugly around the hardware. Configuration (b) involves applying micrometeoroid-protection standoffs between the ML1 blanket and the hardware; e.g., Cassini employs Mylar accordion strips of 3.81-cm or 6.35-cm height to alleviate the impact of micrometeoroids on sensitive hardware. Configuration (c) involves draping the ML1 blanket over the hardware in a tent-like manner, leaving a substantial distance between the blanket and the hardware; Cassini has several such applications, e.g., for the Fields and Particles Pallet (FPP) and the Propulsion Module Subsystem (PMS).

Note that modeling technique (a) requires, in addition to \( \epsilon_{\text{eff, hr}} \) an effective solar absorptance which depends on the solar absorptivity of the ML1 outer layer as well as the effective emittance of the ML1. In contrast, modeling technique (b) uses directly the emissivity and solar absorptivity of the ML1 outer layer. Therefore, while modeling technique (a) is still being practiced, it is often replaced by modeling technique (b), which has an additional advantage of yielding the outer layer temperature automatically.
A mathematical relationship exists linking the above three definitions of effective emittance. However, its derivation and related theoretical discussion requires substantial space and will be considered elsewhere.

Test Articles, Setup, and Procedure

Test Articles

Blanketed boxes. MLI blankets were tested in pairs each wrapping around a 22.86 cm x 22.86 cm x 22.86 cm aluminum box that was heated from within. Figure 2 depicts the aluminum box on the right and an MLI blanket on the left. The box, which has Mylar standoffs on it, was inserted in the blanket, and the open flap of the blanket was laced closed, then the blanketed box was installed in the vacuum chamber for testing. Figure 3 depicts a pair of blanketed boxes ready for installation in the vacuum chamber.

The identical boxes were made from 0.318 cm thick aluminum 6061-T6 plates. The inside of the boxes were painted black (to help achieve a uniform box temperature) and the outside left as machined. Thermofoil heaters and thermocouples were mounted on the inside of each of the six panels. The top and four side panels were welded together, but the bottom panel (with a 0.953 cm diameter hole at the center) was bolted to the bottom edges of the four side panels with eight #10 bolts. Wires from the heaters and thermocouples were routed out through the center hole, and the bottom panel was secured after all instrumentation inside the box was completed.

Fig. 2 MLI blanket and aluminum box with Mylar standoffs
ML] blankets. Four ML blankets were tested. Their designations and layup designs are as follows:

ML1-A: SSAK + 5EK + 15MN + AK, with micrometeoroid standoffs (the standard layup).
ML1-B: BK + 20EK + AK, with micrometeoroid standoffs (the high temperature layup).
ML1-C: SSAK + 5EK - 15MN + AK, no micrometeoroid standoffs.
ML1-D: Outer blanket layup SSAK - 1513K, inner blanket layup 15MN + AK, scarms staggered, with micrometeoroid standoffs.

The blanket constituents referred to above are:

SSAK: Second surface aluminized Kapton, 1/2 mil thick, ITO (iridium tin oxide)-coated on the front, Nomex scrim reinforced on the back, used for outer layer.
BK: Black Kapton, carbon-filled, 1 mil thick, used for outer layer.
EK: Embossed Kapton, 1/3 mil thick, aluminized on both sides, used for intermediate layer.
MN: Mylar with Dacron net, alternating layers; 1/4 mil thick Mylar aluminized on both sides, used for intermediate layer.
AK: Aluminized Kapton, 1 mil thick, aluminized on both sides, used for inner layer.

Photographs of MLJ-A, MLJ-B, and MLJ-C are shown in Fig. 4, from left to right. A photograph of MLJ-D is displayed in Fig. 5, with the outer blanket being box-shaped on the left, and the inner blanket unfolded on the right. MLJ-A, -B, and -C arc of dimensions 31.53 cm cubed, while MLJ-C, 23.92 cm cubed.

Instrumentation. Thermofoil heaters were mounted on the interior of the boxes, two on each face, with large area coverage to help achieve uniform heating of the boxes. All thermocouples were of Type E (Chrome/constantan),gage 30, and with a copper tab. Fourteen thermocouples were affixed to the interior of each box, the guideline being one thermocouple at the center of each face, and one near each corner of the box.

Thermocouple placement on the blankets followed the same guideline. Thermocouples on the inner and outer layers were paired so that they were directly opposite each other. No thermocouples were placed on the intermediate layers. Typically, each blanket used a total of 28 thermocouples. The chamber shrouds were also provided with thermocouples so that temperatures around the test boxes were monitored.

A guard heater was mounted on the 20 wires that exited the center hole on the bottom plate of each box to control the heat loss to under 0.05 W. Eight DC power
supplies were employed, three for each of the two boxes and one for each of the two guard heaters. The Space Simulator System at JPL’s Environmental Test Lab was utilized for data acquisition and power control.

Test Setup

The tests were conducted in Chamber #20 at the Environmental Test Lab. The chamber has internal shroud dimensions of 68.58 cm diameter by 91.44 cm length. Figure 3 shows the chamber in the background. During installation of the test articles, the boxes were suspended from the chamber top rail with a stainless steel wire, and were anchored to the chamber walls by three Nomex chords to prevent their movement and rotation (the stainless steel wire and Nomex chords conducted very little heat, and are visible in Fig. 3). A LN2-cooled cold plate (seen to the left of Fig. 3, below the chamber door) was employed to separate the two boxes, thereby dividing the chamber into two almost identically conditioned compartments. The cold plate was converted from a used heat exchanger plate and was painted black on both sides. The door shroud was also painted black on the inside and was covered with a 20-layer MLI on the outside to ensure that extraneous heat input from outside the chamber was minimized. The goal of the arrangement was that all sides of the two boxes were viewing surfaces at essentially the same temperatures.

Test Procedure

Each of three test phases was conducted in a vacuum of less than 1x10^-5 torr, and with the chamber shrouds and cold plate controlled first to the LN2 temperature (-185°C), then to -100W, approximately. The box temperatures were targeted to be around 20 and 50°C, respectively, to simulate a “nominal” and a “hot” hardware condition. The heater power required per box for each set of conditions was first estimated, then fine-tuned during the test. For each test phase, following the chamber pump down, the power supply was brought up to a level suitably greater than the intended one, dropping to the intended level only after the box temperature had approached the target value. This “overshooting and slow coating down” technique was employed to speed up the process of attaining steady state, and needed to be practiced with some art. Steady state was regarded as approached if temperatures changed at a rate of no greater than 0.2°C/hr.

After each test phase, which consisted of three or four stages, was completed, a chamber break would occur, the boxes would be removed from the chamber, and a new pair of blankets would replace the pair just tested. And the process of testing would be repeated.

Test Results and Effective Emittance

The test data recorded during the three test phases are presented in Table 1. They are power required (Q) to maintain the box temperature (Tb), the MLI outer and inner layer temperatures (T5 and T6, respectively), at the given chamber shroud temperature (T0). T5, T6, and T0 are averaged temperatures. The box and shroud temperatures do not vary more than 2 or 3%, but the MLI center and corner temperatures differ substantially. For this reason, both TO and T are listed in Table 1, first as the average of the six center temperatures, then on a separate line as the average of the eight corner temperatures, for every test case. In general, center temperatures vary less than corner temperatures; on occasions, some corner temperatures may appear erratically different from the rest of the same MLI. Overall, however, the averaging scheme appears to be quite reasonable, and the effective emittances calculated corroborate with each other very well.

Since the test articles and test setup were designed so that heat losses via the supporting wires and thermocouple and heater wires were negligible, the power input to the boxes is assumed to be completely dissipated through the MLI. Applying Eqs. (1)-(4), these test data were used to calculate eeff, eeffb, and eeffb. The calculated effective emittances are presented in Table 1.

Discussion

Comparison of layups and effect of standoff. As can be seen in Table 1, eeffb, which is sometimes called the traditional effective emittance, appears to be unambiguously determined for all four blanket layups. The average value is 0.026 for MLI-A (the standard layup), 0.031 for MLI-B (the high temperature layup), 0.024 for MLI-C (the standard layup without standoffs), and 0.010 for MLI-D (the duo-blanket with staggered seams). Note that the 0.026 value agrees well with the initial Cassini design guideline of 0.02 ± 0.005 for this size and type of blanket. Also note that deviations of all data from these averages are relatively small. In fact, considering that four different MLI layups were involved in three different test phases, that chamber breaks and rearrangement of test articles occurred between test phases, and that the tests were conducted at several temperature settings, these results exhibit a rather high degree of repeatability.

</table>

It is significant that the effective emittance for MLI-B, the all embossed Kapton layup, is 19% higher than that for MLI-A, the hybrid Kapton-Mylar layup. This gives credence to and quantifies the intuitive feel that many had shared before the test. It is also interesting to note that the effective emittance for MLI-C is 8% lower than that for MLI-A. Both are of the same hybrid Kapton-Mylar layup, yet the tighter fit of MLI-C (less blanket area) as a result of the absence of the micrometeoroid standoffs, actually is able to keep the box warmer. A close comparison between results for test phases la - ld for the two blankets shows that MLI-C kept the box about 2°C warmer by using less power.
Hardware-to-outer-layer effective emittance. It is shown by Table 1 that $\epsilon_{\text{eff,bo}}$ and $\epsilon_{\text{eff,bc}}$ are almost identical. This is so because the radiation resistance from the outer layer to the sink is much less (roughly 10 to 40 times) than from the hardware to the outer layer. This explains why applying $\epsilon_{\text{eff,bbo}}$ in modeling scheme (b), Fig. 1, as is often done in spite of being a mismatch, does not cause significant errors. It is believed that most effective emittance data reported in the literature are $\epsilon_{\text{eff,bo}}$, although not specifically clarified. Also, whether the outer layer temperature is identified with that of the center, or corner, or some average of the two, the value of the computed $\epsilon_{\text{eff,bo}}$ is hardly affected.

The intrinsic M1.1 effective emittance. As Table 1 clearly indicates, $\epsilon_{\text{eff,bbo}}$ is very different from $\epsilon_{\text{eff,bbc}}$. In a hardware-M1.1 configuration of type (c), Fig. 1, if the modeling uses $\epsilon_{\text{eff,bbo}}$ instead of the correct $\epsilon_{\text{eff,bbc}}$, substantial errors will result. Both $\epsilon_{\text{eff,bbo}}$, and $\epsilon_{\text{eff,bbc}}$ have entered discussions in the M1.1 literature, but usually without a clear distinction between the two. These results show that a clear distinction is necessary. Physically, the effective emittance based on the inner- and outer-layer temperatures is an intrinsic characteristic of the blanket layup, while the traditional effective emittance also incorporates effects of the hardware surface emissivity, the M1.1 inner- and outer-layer emissivity, the hardware-to-blanket gap geometry, the standoff if any, and the emissivity and geometry of the chamber shroud. The latter includes the various “surface resistances” and “space resistances” and hence is expected to be lower than the former.

However, this is just the opposite. Of what Table 1 indicates, that $\epsilon_{\text{eff,bbc}}$ is significantly higher than $\epsilon_{\text{eff,bbo}}$ in most cases. The apparent paradox is the result of applying the appropriate area in the calculation of $\epsilon_{\text{eff}}$, using Eqs. (1) - (4). As noted in Table 1, $\epsilon_{\text{eff,bbo}}$ is based on $A(\text{hwr})$ which is equal to 0.314 m², but $\epsilon_{\text{eff,bbc}}$ is based on $A(M1.1)$ which is equal to 0.597 m² except for M1.1-C. When the underlying area is made the same, the physical argument presented in the preceding paragraph would be borne out. As a matter of fact, $A(M1.1-C)$ is equal to 0.343 m², which is quite a bit closer to $A(\text{hwr})$ than $A(M1.1-A)$; one sees that $\epsilon_{\text{eff,bbc}}$ is indeed smaller than $\epsilon_{\text{eff,bbo}}$ in this case. This points out another important consideration which is not always clear to the analyst. When modeling by scheme (c), Fig. 1, it is $A(M1.1)$ that should be used in conjunction with an $A(M1.1)$-based $\epsilon_{\text{eff,bbc}}$. But when modeling, by scheme (b), one must use $A(\text{hwr})$, and what’s more, one must make sure that the $\epsilon_{\text{eff,bbo}}$ value derived from a certain hardware dimension is applicable to the modeled configuration. The (22.86 cm³) box employed in these tests is representative of many of the instrument sizes for the Cassinispaceshuttle, but blind application of the Table 1 data is strongly warned against.

Note that in Table 1, center- or corner-averaged TO and $\delta$ do not seem to make a great difference when computing $\epsilon_{\text{eff,bbo}}$ for M 1.1-A and M1.1-D. However, the difference shows for M 1.1-B and especially for M1.1-C. This is because corner temperatures vary widely, perhaps due to varying condition of contact with the hardware (recalling that M1.1-C is a snug fit). More importantly, AT between the center-averaged and corner-averaged temperatures is much greater for M1.1-C than for M1.1-A (e.g., 23°C vs. 6°C for $T_c$, and 47°C vs. 25°C for $T_o$). Details of heat loss at and near the scams become important and the simple-minded averaging of corner temperatures is no longer meaningful. Therefore, while values of $\epsilon_{\text{eff,bbo}}$ for M1.1-B and M1.1-C as presented in Table 1 offer a glimpse of the location dependency of effective emittance and a hint of the range of variation, a better understanding of the M1.1 heat loss mechanism involved is essential.

Heat Loss in the Vicinity of Scams

The revelation of dramatic difference between the center and corner temperatures and of the heat loss characteristics in the vicinity of scams came as a bonus. The unexpectedly large center-corner AT’s as discussed above suggested that something might be learned by placing additional thermocouples on the test articles in subsequent test phases, over the inner- and outer-layer surfaces, and especially along the scams. The details of a typical scam and corner for the Cassini M1.1 blankets are shown in Fig. 6. Note that the open flap is to be closed with a Nomex lacing, through the edge holes. This is a typical construction for JPL spacecraft M1.1 over the decades.

Fig. 6 M1.1 scam and corner construction

American Institute of Aeronautics and Astronautics
Figure 7 exemplifies the temperature distribution across a blanket surface, from seam to seam. It is noted that on the blanket inner layer, the temperature at the seam is more than 30°C lower than in the middle, while on the outer layer, the seam temperature is higher than that at the center by more than 70°C. These differences are more accentuated than indicated in Table 1 because the corner thermocouples were located at some distance away from the seams. It is reasoned that, at the seam, the stitches pinch the MLI layers together and cause a “thermal short”; this brings the outer- and inner-layer temperatures closer to each other at the seam than elsewhere.

Utilizing the outer layer temperatures and emissivity, and the shroud temperature and emissivity, the local heat losses were computed, and the results are presented in Fig. 8 as a function of distance from the left seam. The heat loss varies from less than 3 W/m² at the center to almost 30 W/m² at the seam, based on A(MLI). With the understanding that in-layer heat transfer is negligible compared to the outflow normal to the MLI (as can be verified by calculation), local effective emittance (i.e., ε_eff) was then calculated using the inner and outer layer temperatures and the heat losses of Fig. 8. The results are plotted in Fig. 9, where it is seen that local effective emittance varies from a low of 0.006 to a high of almost 0.15.

The average effective emittance must lie somewhere in between, depending on the size of the blanket, and other hardware configuration parameters. The larger the blanket, the more the low emittance in the middle will weigh on the average. It is thus clear that, in selecting a value for the MLI effective emittance, analysts must consider the size and other geometric factors of the MLI, and how the MLI will be fabricated and assembled. Figure 9 gives suggestion as to the upper and lower bounds of effective emittance that one may select in conducting sensitivity studies, as well as points to a way of improving MLI thermal performance; i.e., by minimizing the seam losses. For a small box such as used in these tests, Fig. 8 clearly shows the importance of heat losses in the vicinity of seams. It thus follows if seam losses are minimized by avoiding through seams, then the performance of the MLI can be substantially improved. The 2.6-fold reduction of effective emittance exhibited by MLI-D, as pointed out earlier, proves the point.

Conclusions

The Kapton-Mylar hybrid layup and the all-Kapton high temperature layup are designed to respond to the high temperature environments that the Cassini spacecraft will encounter in its mission to Saturn. Thermal development tests have been conducted to characterize their effective emittance and verify that these MLI designs can provide adequate thermal performance. The test results have yielded effective emittance for four different MLI layups/configurations at several temperature
settings. These results have high repeatability and are amenable to consistent physical interpretations.

The all-Kapton layup was shown to be leakier (19% higher effective emittance) than the hybrid layup, bearing out a long-held intuitive conjecture. The MLI fabricating technique of duo-layup and staggering seams has been applied to enhance blanket performance over the years, but these tests gave the first quantitative proof that the technique does work, and with a dramatic 2.6-fold performance gain.

Attention has been called to the distinction between three effective emittance definitions, all having relevance to Cassini hardware-MLI configurations. The intrinsic effective emittance, ε_{eff, int}, should be used in situations where the MLI drapes over the hardware in a tent-like manner (e.g., the PMS and FPP). On the other hand, the traditional effective emittance, ε_{eff, tr}, should be applied where the MLI wraps around the hardware snugly or is spaced off by the micrometeoroid standoffs.

The observation of large temperature difference between the center and seam of a blanket (up to 70°C) was unexpected. But a follow-up investigation led to a welcome revelation of the heat loss characteristics in the vicinity of seams. The quantitative results obtained on temperature distribution over a blanket surface, and location dependency of heat loss and effective emittance shed light on a major MLI heat loss mechanism. They offer a guide for thermal analysts in conducting sensitivity studies, and explain the superior performance of the duo-layup, staggered-seam MLI construction.

Acknowledgment

The work described in this paper was carried out by the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration. The authors appreciate the cooperation and assistance provided by the following individuals during the course of the tests: J. Real, R. Martinez, A. Burrows, '1'. Fisher, P. Martin, G. Laugen, E. Bailey, D. Perry, R. Okamoto, L. Johnson, and H. Winter. P. Stevens measured the optical properties. M. Greenfield contributed some cogent remarks, and K. Juanero and J. van Lepp helped plot the figures.
