ABSTRACT
We have developed a technique that allows SIM to measure relative stellar positions with an accuracy of 1 micro-arcsecond at any time during its 5-yr mission. Unlike SIM's standard narrow-angle approach, Gridless Narrow Angle Astrometry (GNAA) does not rely on the global reference frame of grid stars that reaches full accuracy after 5 years. GNAA is simply the application of traditional single-telescope narrow angle techniques to SIM's narrow angle optical path delay measurements. In GNAA, a set of reference stars and a target star are observed at several baseline orientations. A linearized model uses delay measurements to solve for star positions and baseline orientations. A conformal transformation maps observations at different epochs to a common reference frame. The technique works on short period signals (P=days to months), allowing it to be applied to many of the known extra-solar planets, intriguing radio/X-ray binaries, and other periodic sources. The technique's accuracy is limited in the long-term by false acceleration due to a combination of reference star and target star proper motion. The science capability 1 micro-arcsecond astrometric precision – is unique to SIM.

Keywords: Space Interferometry Mission, relative astrometry, extra-solar planets, binary stars.

1. INTRODUCTION
The Space Interferometry Mission (SIM) is capable of detecting and measuring the mass of terrestrial planets around stars other than our own. It can measure the mass of black holes and the visual orbits of radio and x-ray binary sources. There is no doubt that with the successful conclusion of the SIM mission, the Universe will contain many newly discovered planets and many breakthroughs in our understanding of complex astrophysical processes.

SIM achieves its high precision in the so-called "narrow-angle" regime. This is defined by a small (1") diameter field in which the position of a target star is measured with respect to a set of reference stars. The observation is performed in two parts: first, SIM observes a grid of stars that spans the full sky. After a few years, repeated observations of the grid allow one to determine the orientation of the interferometer baseline. Second, throughout the mission, SIM periodically observes in the narrow-angle mode. Every narrow-angle observation is linked to the grid to determine the precise attitude and length of the baseline.

The narrow angle process demands patience. It is not until five years after launch that the SIM data can be reduced to yield the ultimate accuracy. The accuracy is best at mid-mission, and a factor of 2 worse at the beginning and end of the mission.

This manuscript describes a process for obtaining high-precision narrow-angle measurement with SIM at any epoch. We show through analysis and simulations that SIM can obtain vast accuracy and can detect extra-solar planets with a few days of observation, and without relying on a high-precision grid of reference stars. The process can be applied as early as during the first six months of in-orbit calibration (IOC). We call this technique Gridless Narrow Angle Astrometry, or GNAA.

The motivations are two-fold. First, and obviously, it is an insurance policy against a catastrophic mid-mission failure. Second, early results and a technique that can duplicate those results throughout the mission will give the mission analysts important experience in the proper use and calibration of SIM.
2. GRIDLESS NARROW ANGLE ASTROMETRY (GNAA)

2.1. SIM’s Baseline Approach

The process of performing narrow angle astrometry with SIM is in principle straightforward: SIM derives the baseline orientation, length, and delay constant by observing stars whose positions are known to a few microarcsec (mas). These are referred to as "grid stars" as they are part of the high-precision all-sky grid that is the basis for SIM’s narrow-angle and wide-angle astrometry (reference: Swartz). It then observes the target and nearby reference stars, ultimately computing the position of the target relative to the reference stars along the direction of the baseline. The baseline is then rotated (nominally within a few days) and the stars are re-observed to measure the position on the orthogonal axis.

Narrow angle accuracy is limited by the number of grid stars and the accuracy of their measured positions. Grid stars are spread over a 15-degree diameter “tile” while the target and reference are confined to a 1-degree field near the center of the tile. To first order, for a given grid-star angular error e, the narrow angle error is \( e/15 \), but this is subject to the intermediate step of baseline determination. Simulations show that on average 6 grid stars are required per tile if grid star errors of 4 mas r.m.s. are to contribute < 0.3 mas r.m.s. to the narrow angle solution.

The narrow angle measurement process does not achieve its full accuracy until the end of the mission because grid star positions, proper motions, and parallaxes are not known to their potential accuracy until then. A first grid star campaign is planned during the initial 6-month in-orbit checkout (IOC), but it will be \( \approx 1 \) year before an accurate parallax (\( \approx 15 \) mas) is determined over a significant fraction of the sky. Thus the SIM science teams do not plan to report accurate narrow angle results in a timely fashion, even for known short-period systems. The baseline narrow angle technique relies on the grid star campaign, evolving in accuracy over the 5-year mission life.

2.2. Efficiency

Narrow angle measurements are scheduled in an efficient manner to take advantage of grid star observations and other objects of interest within a tile. The narrow angle measurements are chopped into 1-minute long observations (30 seconds of integration, 30 seconds of slew and acquisition) with 10 observations per star per hour. Observation of a target and 2 reference stars would then require 30 minutes per hour. Observation of 6 grid stars before and after the narrow angle measurements would use another 12 minutes. In theory a full 2-d measurement could be completed in about 1.5 hr.

Compared to the technique proposed below, the SIM narrow angle paradigm is more efficient. The new approach requires narrow angle observation of 4 reference and 1 target star, requiring the full hour (ten 1-minute long observations of 6 objects) to complete a cycle. Further, the new technique requires a minimum of 3 baseline pointings to make one 2-d measurement. After 3 hours, a narrow angle measurement is made on one interesting target. Thus the efficiency is reduced by a factor of 2, depending on how the grid stars are bookkept. The advantage of course is that the measurement is good to 1 mas after just 3 hours whereas the standard SIM approach requires >2 yr to make this claim.

2.3. A New Technique: GNAA

Narrow angle astrometry is nothing more than relative-angle astrometry; one measures the position of a target star with respect to a set of reference stars. In traditional narrow angle astrometry, a photographic plate or charge-coupled detector (CCD) stares at a field in successive observations. The field’s reference stars are used to anchor a least-squares conformal transformation that matches the scale, rotation, translation, and potentially higher order angular terms into a common reference frame. The transformation is then applied to the target star whose motion is observed relative to the reference frame.

The conformal transformation absorbs several instrumental parameters that are of no consequence to relative observational accuracy. Changes in the telescope focal length are seen as plate-scale changes while telescope pointing errors are simply field translations, and detector rotation results in field rotation. Because one only measures the relative positions of the stars, absolute scale of measured parameters is lost, but the relative accuracy is still as good as the a priori knowledge of the field, i.e. 100 milli-arcsec (mas) over 1 degree, or 3e-5 if the reference star catalog positions are good to 100 mas. The minute absolute scale error when applied to the small reflex motion of the target stars is dwarfed by other factors (e.g. shot and detector noise).
GNAA with SIM is little more than the application of traditional narrow angle techniques to SIM's narrow angle optical path delay measurements. The technique, described in the following paragraphs, allows one to perform micro-arcsecond astrometry without solving for precise values of baseline length, baseline orientation, or the metrology constant term. In GNAA, a set of reference stars and a target star are observed at several baseline orientations. A linearized model is used to solve for star positions and baseline orientations. A conformal transformation is applied to relate the reference and target stars to a common reference frame.

As with narrow angle astrometry at a telescope, the conformal transformation absorbs SIM instrumental parameters. To first order baseline length errors cause field dilation, baseline orientation about the line-of-sight cause field rotation, baseline orientation errors orthogonal to the line-of-sight cause field translation and quadratic field distortion (focus and astigmatism), and the metrology constant term is a translation along the direction of the baseline. The conformal transformation solves the scale, rotation, and translation of the observed reference frame without requiring the intermediate step of exact baseline determination. The absolute scale is lost, but it is estimated with a precision approximately given by the a priori scale knowledge of the field size, as described above.

The most significant advantage of GNAA is that high-accuracy narrow-angle measurements can be made early in the mission. As there is no reliance on highly accurate grid star positions, the technique can be applied as soon as the instrument is calibrated. Thus SIM can obtain important scientific results soon after launch and throughout the early parts of the mission. Further, it is an ideal approach not only for early-mission science, but also for quick study and follow-up of compelling objects demanding immediate results. It is certain that some science will demand accurate results long before the 5-yr mission is concluded.

The disadvantages of GNAA are that it is observationally inefficient, and it suffers from false acceleration determination for long observations (a few uas over 5 years). Unlike the grid-based narrow angle technique that allows sharing of a tile between narrow-angle and other targets, GNAA requires 3 dedicated hours of observation to produce a uas 2-d measurement of the target star. At least 4 reference stars and 3 baseline orientations are needed. This technique is clearly not the choice for producing the bulk of narrow-angle science observations once normal operations begin. Further, GNAA is not the choice for observing periodic effects with periods 5 yr. The combination of arcsec/yr target star motion with milli-arcsec/yr reference star motion results in unobservable frame rotation that causes uas target star accelerations after several years.

3. ANALYSIS

The analysis is set up in two parts. First, we show that given a set of stars, baseline orientations and the corresponding delay measurements, there exists a transformation that allows one to determine the star positions from the delay measurements under certain conditions. We describe the null space of the solution, which consists of translation, rotation, scale, and quadratic displacement degrees of freedom. The relative star positions are solved modulo the null space.

Second, we show how observations at different epochs are mapped to a common epoch through a matrix that incorporates the aforementioned null space. Our error analysis reveals that the target star motion suffers from a long-term false acceleration caused by the proper motions of the target and reference stars. This was originally predicted by Shao, and our analysis confirms the predicted magnitude of the effect.

3.1. Proof of GNAA Principal

Let \( D \subset \mathbb{R}^2 \) be a subset of the open unit disc including the origin and let \( \Psi : D \to S \), where \( S \) is the unit sphere:

\[
\Psi(u, v) = (u, v, \gamma(u, v)); \quad \gamma(u, v) \equiv \sqrt{1 - u^2 - v^2}
\]

Star positions in the field of regard are parameterized by \( \Psi \), that is we write

\[
s_i = (u_i, v_i, \gamma(u_i, v_i)).
\]

Stellar positions are estimated using linearized equations about nominal \textit{a priori} positions of the stars and baseline vectors. Within the linear approximation, the true and \textit{a priori} star positions are related as

\[
s_i = s^0_i + \delta s_i,
\]
where $\delta s_i$ is a tangent vector to the sphere at $\delta i$.

$\delta s_i$ is parameterized in the following way. Let $\Psi_*(u, v)$ denote the differential of the map $\Psi$ at the point $(u, v)$. Then $\Psi_*$ maps a tangent vector in $D$ to a tangent vector on the sphere at $\Psi(u, v) = (u, v, \gamma(u, v))$ via

$$\Psi_*(u, v) \begin{bmatrix} h_1 \\ h_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -u/\gamma & -v/\gamma \end{bmatrix} \begin{bmatrix} h_1 \\ h_2 \end{bmatrix},$$

for any tangent vector $h = (h_1, h_2)$ in $D$.

In the narrow field, the set of delay measurements $d_{ij}$ are generated via

$$d_{ij} = (s_i, b_j) + c_j + \eta_{ji}; ~ i = 1, \ldots, N, ~ j = 1, \ldots, M$$

where $b_j$ is the interferometer baseline vector, $c_j$ is the interferometer constant term associated with the baseline vector, and $\eta_{ji}$ is the noise in the measurement. Neither $b_j$ nor $c_j$ are known with sufficient precision, and hence they must either be estimated or eliminated from the set of equations to determine the science position vector.

Writing $b_j = b^0_j + \delta b_j$, where $b^0_j$ is the a priori estimate of the baseline vector, (5) becomes (ignoring the noise term in the sequel)

$$d_{ij} = (s_i, b^0_j + \delta b_j) + c_j$$

Hence,

$$d_{ij} - (s_i, b^0_j) = (\delta s_i, b^0_j) + (\delta b_j, s_i^0) + c_j,$$

where the left side of the equation is known: $d_{ij}$ are the measurements and $(s_i, b^0_j)$ is the expected delay derived from a priori knowledge.

Now let $\Pi$ denote the projection $\Pi(x_1, x_2, x_3) = (x_1, x_2)$ defined for any 3-vector $x = (x_1, x_2, x_3)$. (Thus when $\Pi$ is restricted to the unit sphere, $\Pi = \Psi^{-1}$.) Using the tangent vector description we have

$$\langle \delta s_i, b^0_j \rangle = \langle b^0_j, \Psi_*(u_i, v_i)h_l \rangle$$

$$= \langle \Psi_*(u_i, v_i)b^0_j, h_l \rangle$$

$$= \langle \Pi b^0_j, h_l \rangle + O(\max\{|u_i|, |v_i|\}, |b^0_j| |h_l|),$$

where $b^0_j$ denotes the third component of the vector $b^0_j$. To get a handle on the magnitude of the $O$ term, note that the narrow angle scenario restricts the field to a 1 deg diameter so that $|u_i|, |v_i| < 0.1$. Then if the baseline is controlled to within one arcmin of the $u - v$ plane and the a priori error on the star position is on the order of 30mas, the $O$ term contributes 2.5pm of delay error. Hence, there are no operational restrictions to deleting this term and assuming the model has the form

$$d_{ij} - (s_i, b^0_j) = \langle \Pi b^0_j, h_l \rangle + (\delta b_j, s_i^0) + c_j,$$

Next define the $2 \times 2$ rotation matrix $E$,

$$E = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},$$

and consider the decomposition of $\delta b_j$ as

$$\delta b_j \epsilon E \Pi b^0_j + \epsilon E (\Pi b^0_j) + \delta b^0_j$$

where again $\delta b^0_j$ denotes the third component of the vector $\delta b_j$. Thus we may write

$$\langle s_i^0, \delta b_j \rangle + c_j = \epsilon \langle \Pi b^0_j, \Pi b^0_j \rangle + \epsilon (\Pi b^0_j, E^T (\Pi b^0_j)) + c_j + \delta b^0_j q_j.$$
Let $\rho_i^2 = u_i^2 + v_i^2$. Then $\gamma_i \approx 1 - \rho_i^2/2$, and

$$c_j + \delta b_j^2 \gamma_i = c_j + \delta b_j^2 - \delta b_j^2 \rho_i^2/2.$$  \hfill (16)

Introducing the new constant $c_j \equiv c_j + \delta b_j^2$, the delay equation becomes

$$d_{ij} - (s_j^0, b_j^0) = \langle \Pi \rho_j^0, h_i \rangle + \epsilon_r (\Pi \rho_j^0, \Pi \rho_j^0) + \epsilon_T (\Pi \rho_j^0, E^T (\Pi \rho_j^0)) - \delta b_j^2 \rho_i^2/2 + c_j.$$  \hfill (17)

The unknown variables in the equation above include $h_i, \ i = 1, \ldots, N, \ \epsilon_r, \ \epsilon_T, \ \delta b_j^2$, and $c_j$. The external metrology subsystem tracks the change in the length of the science baseline vector without interruption during the generation of the entire set of delays in (17). Coupling this with the operational scenario that maintains the interferometer baseline vector in the $u-v$ plane, we may assume that $\epsilon_r$ represents a single unknown. This is to be contrasted with $\epsilon_T, \ \delta b_j^2$, and $c_j$ that we allow to change for each baseline orientation. Hence each of these terms represents an $M$ vector. Now let $X$ denote the entire vector of unknowns:

$$X = \begin{bmatrix} h_1 \\ \vdots \\ h_N \\ \epsilon_r \\ \epsilon_T \\ \delta b_j^2 \\ c \end{bmatrix}.$$  \hfill (18)

Then $X$ is computed to be an $2N + 3M + 1$ vector. However, we will show below that there are a total of 6 redundant degrees of freedom. To characterize these redundant degrees of freedom we write the system of equations (17) as

$$d = A_d X,$$  \hfill (19)

and search for the null space of $A_d$ (written null($A_d$)). We will get these vectors just by eyeballing the situation.

By setting $\epsilon_r = 0, \ \epsilon_T = 0, \ \delta b_j^2 = 0, \ h_i = (\kappa_1, \kappa_2)$, and $c_j' = -\langle \Pi \rho_j^0, h_i \rangle$, we see that this vector is in the null space for any choice of $\kappa_i$. For two independent choices of $\kappa_1$ and $\kappa_2$, let $u_1$ and $u_2$ denote the corresponding vectors in null($A_d$). A third vector in the null space is obtained by setting $\epsilon_T = 0, \ \delta b_j^2 = 0, \ c_j' = 0, \ h_i = \Pi \rho_j^0$, and $\epsilon_r = -1$. Denote this vector as $u_3$. A fourth null space vector is constructed by taking $\epsilon_r = 0, \ \delta b_j^2 = 0, \ c_j' = 0, \ h_i = E^T (\Pi \rho_j^0)$, and $\epsilon_T = -(1, \ldots, 1)$. Let $u_4$ denote this vector. Two other null space vectors are obtained in the following way. Fix $i$ in (17) and set $\epsilon_r, \ \epsilon_T, \ c_j' = 0$. For each $i$, consider solutions to the system of equations

$$\Pi \rho_j^0 h_i + \delta b_j^2 \rho_i^2/2 = 0, \quad j = 1, \ldots, M.$$  \hfill (20)

Let $B$ denote the $2 \times 2$ matrix

$$B = \begin{bmatrix} \Pi \rho_j^0 \\ \Pi \rho_j^0 \end{bmatrix},$$  \hfill (21)

where $\Pi \rho_j^0$ is row $j$. $B$ is invertible so there exist $\delta b_j^2$ and $\delta b_j^2$ such that

$$B h_i + \rho_i^2/2 \begin{bmatrix} \delta b_j^2 \\ \delta b_j^2 \end{bmatrix} = 0,$$  \hfill (22)

with $h_i = \rho_i^2/2(1, 0)$. By setting

$$\delta b_j^2 = -\langle b_j^0, B^{-1} \begin{bmatrix} \delta b_j^2 \\ \delta b_j^2 \end{bmatrix} \rangle, \quad j = 3, \ldots, M$$  \hfill (23)

we see that $h_i = (1, 0)$ and $\delta b_j^2$ as defined in (22)–(23) satisfy (17) for all $i$. Thus the vector with these components is in null($A_d$). The same construction using $h_i = \rho_i^2(0, 1)$ yields another vector in the null space. Designate these two vectors $u_5$ and $u_6$. 

Now introduce $\Gamma: \mathbb{R}^{2N+3M+1} \to \mathbb{R}^{NM}$ by

$$\Gamma X = \begin{bmatrix} h_1 \\ \vdots \\ h_N \end{bmatrix},$$

and define $h_i = \Gamma u_i, \; i = 1, \ldots, N$. The $h_i$ are simply the star position components of the null vectors. $h^1$ and $h^2$ correspond to a translation of the field, $h^3$ corresponds to a dilation of the field, $h^4$ is a rotation of the field, and $h^5$ and $h^6$ are quadratics in the $u$ and $v$ directions, respectively. So in general any two solutions of (19) with $h$ and $h'$ representing the star position components of the solutions are related as

$$h = h' + \sum_{i=1}^{6} \alpha_i h^i,$$

for some scalars $\alpha_i$. Let $A^+$ denote the pseudoinverse of $A_d$. Then the solution of the star position coordinates given by

$$\hat{h} = \Gamma A_d^+ d$$

is of fundamental interest. This solution has no component in the span of $\{h^i\}_{i=1}^{6}$ and is useful for characterizing the stability properties of the GNAA method. The error multipliers on the star positions, once the null space has been removed, are quite favorable (near unity) for reasonable geometries. In many applications of GNAA it is also possible to ignore the contribution of $h^5$ and $h^6$. Conditions where this is possible include the cases where the field of regard is very small (much less than 1 degree), or when the reference stars are located on a thin annular disc about the center of the field. In this case the $u_5$ and $u_6$ are nearly indistinguishable from $u_1$ and $u_2$.

The minimum number of stars and baseline orientations required to determine the star positions (modulo the null space) is fixed by the number of measurements, $N \times M$, and the number of degrees of freedom (DOFs). We have fixed the baseline length for the $M$ observations, so there are $2M + 1$ baseline DOFs, plus $M$ metrology constant terms, to go along with the $2N - 6$ (6 being the dimension of the null space) stellar DOFs. Thus the number of stars and baselines is set by

$$NM \geq 2N + 3M - 5.$$ (27)

This is solved using a minimum of $N = 4$ stars and $M = 3$ baselines.

### 3.2. Astrometric Formulation

Over a small field of regard ($1^\circ$) the curvature of the sphere can be effectively ignored, and it suffices to model points on the sphere as lying in a plane. Given a set of $N$ reference stars, $s_i$, we will assume their motion is restricted to such a plane and obeys a law of the form

$$s_i(t) = s_i(0) + v_i t,$$

where $t$ is time and $v_i$ is the proper motion vector. We will actually assume that $v_i$ represents an unknown proper motion, i.e. the residual between the true and $a \text{ priori}$ proper motion vectors. The target star, $s_T$, has a similar evolution:

$$s_T(t) = s_T(0) + v_T t + \phi(t).$$ (29)

For the target star we will assume that $v_T$ is known; the objective is to identify $\phi(t)$.

GNAA works in the following way. The standard model for the positions of the reference and target stars from which estimates are derived from delay measurements has the form

$$\hat{s}_i(t) = \hat{s}_i(0) + h_i(t), \; \; i = 1, \ldots, N \; \; \hat{s}_T(t) = \hat{s}_T(0) + tv_T + h_T(t),$$

where $\hat{s}_i(0), \hat{s}_T(0)$ are the estimates of the positions of the reference and target object at an initial time $t = 0$ determined from the first set of measurements, and $h_i(t)$ are correction terms determined from measurements. (So $h_i(0) = 0$.) The $h_i$ can only be determined up to a translation, rotation, or scale factor. The latter ambiguity is due to the unknown absolute scale of the instrument. The GNAA principal (proved in the previous section) implies that there exists a transformation $A(t)$,

$$A(t)s = k(t) + \varepsilon(t)s + w(t)s,$$

where
such that
\[ s_i(t) - \hat{s}_i(t) = A(t)\hat{\epsilon}_i(t) \] (32)
for all \( i = 1, \ldots, N, T \) and for any set of estimates of the star positions taken at any time \( t \geq 0 \). Here \( \kappa \) is a two-vector, \( \epsilon \) and \( w \) are scalars, and \( E \) is the matrix
\[ E = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}. \] (33)

Now (32) also holds for \( t = 0 \), i.e.
\[ s_i(0) - \hat{s}_i(0) = A(0)\hat{\epsilon}_i(0). \] (34)

It is easy to see that the set of maps of the form (31) are closed under addition, so in particular \( A_T = A(t) - A(0) \) is also of the form (31). With this in mind we compute using (32) and (34)
\[ s_i(t) - s_i(0) = \hat{s}_i(t) - \hat{s}_i(0) + A(t)\hat{\epsilon}_i(0) - A(0)\hat{\epsilon}_i(0) \] (35)
\[ = \hat{s}_i(t) - \hat{s}_i(0) + A_T\hat{\epsilon}_i(0) \] (36)
after using \( \hat{s}_i(t) = \hat{s}_i(0) + \hat{h}_i(t) \) and deleting terms of second order. Because the proper motion of the target star is very large, we will retain its second order contribution below to obtain
\[ s_T(t) - s_T(0) = \hat{s}_T(t) - \hat{s}_T(0) + A_T[\hat{s}_T(0) + t\hat{v}_T] + tA(0)v_T. \] (37)

The objective is to determine the left side of (37) above; this is the motion of the target star. On the right side above, the unknowns are the transformations \( A_T \) and \( A(0) \). \( A(0) \) only contributes a linear term, while \( A_T \) can be determined, in principle, from (36). However, an error will arise because \( A_T \) cannot be determined exactly from (36) since the model of the left side of the equation contains proper motion errors.

3.3. Error Analysis.

Introduce the \( 2N \times 4 \) matrix \( X \)
\[ X = \begin{bmatrix} I_{2 \times 2} & s_1 & E s_1 \\ & \vdots & \vdots & \vdots \\ I_{2 \times 2} & s_N & E s_N \end{bmatrix}, \] (38)

and the 4 component parameter vector \( p \) that characterizes \( A_T \) via

\[ A_T s = \begin{bmatrix} p_1 \\ p_2 \end{bmatrix} + p_3 s + p_4 Es. \] (39)

Then (36) can be written as
\[ t\nu = \hat{s} + Xp, \] (40)

where
\[ \nu = \begin{bmatrix} v_1 \\ \vdots \\ v_N \end{bmatrix}, \] and
\[ \hat{s} = \begin{bmatrix} \hat{s}_1(t) - \hat{s}_1(0) \\ \vdots \\ \hat{s}_N(t) - \hat{s}_N(0) \end{bmatrix}. \] (41)

Thus, \( p = X^\dagger[v - \hat{s}] \), where \( X^\dagger \) denotes the pseudoinverse of \( X \). But since there is no knowledge of the proper motions \( v_i \), the estimated transformation uses \( \hat{p} = -X^\dagger \hat{s} \) instead, and an error of \( t\delta p \) arises where
\[ \delta p = X^\dagger v. \] (42)

Let \( \hat{A}_T \) denote the transformation in (39) using \( \hat{p} \), and again consider (37). The last two terms on the right are the corrections to the position estimate differences using the transformations \( A_T \) and \( A(0) \). However, the best we can do is use \( \hat{A}_T \). The resulting error in the (change in) position of the target star, call it \( \delta s_T(t) \) is.
\[ \delta s_T(t) = (A_T - \hat{A}_T)[\hat{s}_T(0) + t\hat{v}_T] + tA(0)v_T. \] (43)
From (39), (42), and (43) we see that
\[
\delta y_T(t) = t \left[ \frac{\delta p_1}{\delta p_2} + \delta p_3 \delta y_T(0) + \nu_T \right] + t \delta p_4 \delta y_T(0) + t \nu_T + \delta A(0) \nu_T. \tag{44}
\]

Now, from (42) it evident that \( \delta p \) is linear with time; hence the acceleration error \( \alpha \) is given by the coefficients of the quadratic (in \( t \)) terms above:
\[
\alpha = 2[\delta p_3 \nu_T + \delta p_4 \nu_T]. \tag{45}
\]

Since \( \nu_T \) and \( E \nu_T \) are orthogonal with \( \langle E \nu_T | \nu_T \rangle = 0 \),
\[
|\alpha| = 2|\nu_T||\delta q|, \quad \text{where} \quad \delta q = \begin{bmatrix} \delta p_3 \\ \delta p_4 \end{bmatrix}. \tag{46}
\]

Let \( T \) denote the period of observation. After performing a linear least squares fit to the displacement due to acceleration, \( t \rightarrow \alpha t^2/2 \) over the period \( 0 \leq t \leq T \), the residual error, \( r(t) \) is the quadratic
\[
r(t) = |\nu_T||\delta q| \left( -\frac{1}{6} T^2 + Tt - t^2 \right) \tag{47}
\]
with a peak–to–peak displacement, \( \delta \),
\[
\delta = |\nu_T||\delta q|T^2/4. \tag{48}
\]

It remains to characterize \( \delta q \). Without loss of generality we may assume the origin of our coordinate system is the barycenter of the reference star positions, i.e.
\[
\sum_{i=1}^{N} \delta_i(0) = 0. \tag{49}
\]

By linearity we then also have
\[
\sum_{i=1}^{N} E \delta_i(0) = 0. \tag{50}
\]

Since \( X \) has full rank, \( X^T = (X^T X)^{-1} X^T \). Now define the \( 2 \times 2 \) matrices, \( S_i \) as
\[
S_i = [s_i \ E s_i]. \tag{51}
\]

Note that \( X^T X \) is the \( 4 \times 4 \) matrix
\[
X^T X = \begin{bmatrix} N f_{2 \times 2}^2 & \sum_{i=1}^{N} S_i \\ \sum_{i=1}^{N} S_i^T & \sum_{i=1}^{N} S_i^T S_i \end{bmatrix}. \tag{52}
\]

But \( \sum S_i = 0 \) by (49) and (50), and
\[
\sum_{i=1}^{N} S_i^T S_i = \sum_{i=1}^{N} |s_i|^2 f_{2 \times 2}. \tag{53}
\]

Hence, \( X^T X \) is the diagonal matrix
\[
X^T X = \begin{bmatrix} N f_{2 \times 2}^2 & 0 \\ 0 & \sum_{i=1}^{N} |s_i|^2 f_{2 \times 2} \end{bmatrix}. \tag{54}
\]

Thus,
\[
\delta q = \frac{1}{\sum_{i=1}^{N} |s_i|^2} \begin{bmatrix} \sum_{i=1}^{N} s_i^T v_i \\ \sum_{i=1}^{N} (E s_i)^T v_i \end{bmatrix}, \tag{55}
\]

and
\[
|\delta q| = \frac{1}{\sum_{i=1}^{N} |s_i|^2} \left( \sum_{i=1}^{N} |s_i|^2 \sum_{i=1}^{N} (E s_i)^T v_i \right)^{1/2}. \tag{56}
\]
Expressions (47,48), (55) and (56) expose the relevant parameters of the peak-to-peak quadratic error. For example, if we assume that the proper motions $\{v_i\}$ are zero mean independent random vectors with common variance $\sigma_v^2$, we find the peak-to-peak displacement is

$$
\delta_{\text{random}} = \frac{\sqrt{2}|v_T|\sigma_v T^2}{4\sqrt{\sum_{i=1}^{N} |s_i|^2}}.
$$

(57)

Hence, a $1/\sqrt{N}$ improvement in the error is realized with increasing the number of reference stars, while a linear improvement is obtained by increasing the separation of the reference stars. In general, without the statistical assumption, there is no advantage to using more stars.

### 3.4. Example of False Acceleration

Shao\(^3\) created the following example: the reference frame contains two stars, one at the origin, the other on the v-axis. They are moving with an apparent velocity of 1 milli-arcsec yr\(^{-1}\) in opposite directions along the u-axis. Thus the reference frame has a non-zero angular momentum. The target star is located off to the side and moves with a velocity of 1 arcsec yr\(^{-1}\) in the v direction. In our formulation, this is expressed by

$$
s_1 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \quad s_2 = \frac{\pi}{180} \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad s_T = \frac{\pi}{180} \begin{bmatrix} \sqrt{2} \\ \sqrt{2} \end{bmatrix},
$$

(58)

and

$$
v_1 = \frac{4.86 \times 10^{-9}}{\text{yr}} \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad v_2 = \frac{4.86 \times 10^{-9}}{\text{yr}} \begin{bmatrix} -1 \\ 0 \end{bmatrix}, \quad v_T = \frac{4.86 \times 10^{-6}}{\text{yr}} \begin{bmatrix} -1 \\ 0 \end{bmatrix}.
$$

(59)

With respect to barycentric reference star coordinates, we have

$$
s_1 = \frac{\pi}{180} \begin{bmatrix} 0 \\ -\frac{1}{2} \end{bmatrix}, \quad s_2 = \frac{\pi}{180} \begin{bmatrix} 0 \\ \frac{1}{2} \end{bmatrix}.
$$

(60)

Using these values in (48) and (56) together with a 5 year observation period, $T = 5$, leads to the displacement

$$
\delta \approx 3.48\mu\text{as}.
$$

(61)

### 4. SIMULATION

We demonstrate the GNAA technique with the simulation of 55 Cnc (P=14.6 d) described here. The simulation shows that given a set of stars $R$ with only a coarse a priori knowledge of their positions, the target star position can be measured with $\approx\text{1 uas}$ accuracy for extended periods of time.

Based on the radial velocity measurements of the innermost planet around 55 CNC\(^4\), the system is expected to have an astrometric reflex amplitude of 8 uas for the inner planet. While we have not simulated the second component (P=44.3 d, a=0.24 AU\(^2\)), it too is detectable by GNAA with an amplitude of $\approx 4.5$ uas. The outermost planet, with its 14-yr period and >2 mas signal, is easily detectable (though only a fraction of the orbit is observed during the SIM lifetime), but only because the signal is >> the false acceleration due to frame rotation. The outer planet would be detected during the normal course of SIM narrow-angle observations – it is not a candidate for GNAA observations. However, the inner planet would NOT be detected. The nominal SIM narrow-angle observational scenario calls for $\approx 10$ visits/target/yr, compared to 25 orbits/yr for the inner planet. The second planet might be detected (8 orbits/yr) depending on the details of SIM scheduling. Without GNAA measurements, additional planets with signals of a few uas would be masked by the ‘noise’ from the unseen inner planets.

The set of stars $R$ was chosen over a 1° field-of-regard (FOR). The stars in $R$ have an a priori positional knowledge of 100 mas. This could be easily obtained using ground based observations with a small telescope for stars not in the Hipparcos or Tycho catalogs. $R$ is observed at 3 baseline orientations such that the baseline is rotated about the line of sight $s$ in 60° steps. The 60° steps are assumed to be accurate to +/- 1°.5 as is the positioning of the baseline cant angle (out of the $s \times B$ plane). The baseline orientation is assumed to be known to 1 arcsec with information provided by star
The GNAA technique has been studied in some detail but much work remains. The GNAA process ultimately needs to be described in the same analytical framework as the SIM grid and standard narrow angle reductions. Noise propagation and parametric sensitivities will be studied. In doing this, one hopes to describe an optimized process that makes more efficient use of grid stars and precious narrow angle observing time.

This work was performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.
Figure 1. a) is 55 Cnc and the surrounding field of reference stars. Only the nearest bright reference stars (shown) are used. b) shows the result of 30 daily observations of 55 CNC. Each day, the baseline is oriented to 3 positions rotated 60° about the line of sight to the target. For demonstration purposes, the 8 uas signal is assumed to be a pure North-South sine wave. The R.A. axis thus indicates the noise level. Given the simulation parameters described above and this particular set of reference stars, the astrometric precision is 1.0 uas on each axis for each 3-baseline (3-hour long) observation. The reference frame has deformed by up to 300 mas due to proper motions of the reference stars. The relative proper motion of the target star has been fitted and removed.
