The United States has successfully landed five robotic systems on the surface of Mars. These systems all had landed mass below 0.6 metric tons (t), had landed footprints on the order of hundreds of km and landed at sites below -1.4 km MOLA elevation due the need to perform entry, descent and landing operations in an environment with sufficient atmospheric density. At present, robotic exploration systems engineers are struggling with the challenges of increasing landed mass capability to 0.8 t while improving landed accuracy to tens of km and landing at a site as high as +2 km MOLA elevation for the Mars Science Laboratory project. Meanwhile, current plans for human exploration of Mars call for the landing of 40-80 t surface elements at scientifically interesting locations within close proximity (tens of m) of pre-positioned robotic assets. This paper summarizes past successful entry, descent and landing systems and approaches being developed by the robotic Mars exploration program to increased landed performance (mass, accuracy and surface elevation). In addition, the entry, descent and landing sequence for a human exploration system will be reviewed, highlighting the technology and systems advances required.

Nomenclature

\[ A = \text{aerodynamic reference area, m}^2\]

\[ \Delta V = \text{propulsive velocity change, m/s}\]
\[ \tau = \text{atmospheric opacity}\]

I. Introduction

The United States has successfully landed five robotic systems on the surface of Mars. These systems all had landed mass below 0.6 metric tons (t), had landed footprints on the order of hundreds of km and landed at sites below -1.4 km MOLA elevation due the need to perform entry, descent and landing operations in an environment with sufficient atmospheric density.¹

Today, robotic exploration systems engineers are struggling with the challenges of increasing landed mass capability to 1 t while improving landed accuracy to 10’s of km and landing at a site as high as +2 km MOLA elevation for the Mars Science Laboratory project.²³ Subsequent robotic exploration missions under consideration for the 2010 decade, e.g., Mars

Sample Return and Astrobiology Field Laboratory, may require a doubling of this landed mass capability. To date, no credible Mars EDL architecture has been put forward that can safely place a 2 t payload at high elevations on the surface of Mars at close proximity to scientifically interesting terrain. This difficulty is largely due to the Mars program’s continued reliance on Viking-era space qualification technology, which is reaching its limits.

Current plans for human exploration of Mars call for the landing of 40-80 t surface elements at scientifically interesting locations within close proximity (tens of m) of pre-positioned robotic assets. These plans require a simultaneous two order of magnitude increase in landed mass capability, four order of magnitude increase in landed accuracy, and an entry, descent and landing operations sequence that may need to be completed in a lower density (higher surface elevation) environment. This is a tall order that will require the space qualification of new EDL approaches and technologies.

In this investigation, the technology challenges associated with improving our landing site access and landed mass capability are reviewed. Approaches being investigated by the robotic Mars exploration program to increase landed mass capability to 1 t while improving landed accuracy to tens of km and landing at a site as high as +2 km MOLA elevation will be described. It will be shown that this class of mission may be the limit for the Viking-era EDL technology that has served us so well for decades. In addition, the entry, descent and landing sequence for a human exploration system will be reviewed, highlighting the technology and systems advances required for this grand challenge.

II. Mars EDL Challenges

Mars entry, descent and landing is fraught with systems engineering challenges. These challenges emanate from: (a) an atmosphere which is thick enough to create substantial heating, but not sufficiently low terminal descent velocity, (b) a surface environment of complex rocks, craters, dust and terrain patterns, and (c) the cost of replicating a Mars-relevant environment for space flight qualification of new EDL technologies. In the following discussion, each of these EDL challenges will be addressed and the resulting system impact presented.

A. Atmospheric Density, Opacity and Landing Site Elevation

Relative to the Earth, the Mars atmosphere is thin, approximately 1/100th in atmospheric density (see Fig. 1). As a result, Mars entry vehicles tend to decelerate at much lower altitudes and, depending upon their mass, may never reach the subsonic terminal descent velocity of Earth aerodynamic vehicles. Figure 2 shows typical ballistic EDL trajectories for the Earth and Mars; whereas, Figure 3 presents terminal descent velocity at Earth and Mars as a function of entry mass (or ballistic coefficient). Note that on Mars, only entry systems with β below about 50 kg/m² have the ability to deliver payloads to subsonic conditions, and only then at altitudes near the surface (below about 10 km). While Earth and Mars have large
differences in size and mass (which directly affects entry velocity through gravitational attraction), the largest difference on EDL systems design is the thin Mars atmosphere. As one example, because hypersonic deceleration occurs at much lower altitudes on Mars than on the Earth, the time remaining for subsequent EDL events is often a concern. On Mars, by the time the velocity is low enough to deploy supersonic or subsonic decelerators, the vehicle may be near the ground with insufficient time to prepare for landing.

Fig. 1 Earth and Mars atmospheric comparison.

Fig. 2 Altitude-velocity comparison of a typical ballistic entry, descent and landing at Earth and Mars.

Fig. 3 Terminal descent velocity comparison at Earth and Mars as a function of ballistic coefficient, $\beta$. 
Atmospheric variability across a Mars year limits our ability to develop a common EDL system. In addition, significant atmospheric dust content (a random occurrence) increases the temperature of the lower atmosphere, reducing density and requiring conservatism in the selection of landing site elevation. The Mars EDL challenge is exacerbated by the bi-modal Mars surface elevation, where fully half of the surface of Mars has been out of reach of past landers due to insufficient atmosphere for deceleration. Figure 4 provides the Mars elevation area distribution. To date, all successful Mars landings have been to surface sites with elevation less than -1.4 km MOLA. This technology-imposed requirement has eliminated surface exploration of the ancient terrain in a majority of the southern hemisphere (where the MOLA elevation averages +2 km).

![Fig. 4 Mars elevation area distribution. The EDL elevation capability of past successful missions and that proposed for the Mars Science Laboratory is denoted.](image)

Coupling Mars’ low atmospheric density with mission requirements for deceleration has led to entry systems designed to produce a high hypersonic drag coefficient. One such system, the Viking-era 70-deg sphere cone aeroshell has been used on every US Mars landed mission.

B. Mars Surface Hazards

Landing systems are designed to deliver their payloads within the horizontal and vertical velocity envelops of their touchdown equipment. Despite large visual differences, these landing systems have significant commonality. All of these systems initiate while suspended on a parachute near terminal velocity (between 55 and 90 m/s) and within 1 km of the ground. Despite best efforts, the landing systems flown to date are not tolerant to many potential Mars surface hazards.

Mars has several classes of landing surface hazards. For legged landers, rock hazards are one of the largest challenges. Legged landers built so far have had from 20–30 cm of ground clearance (after leg stroke for landing load attenuation). Rock clearance is also required for the propulsion system. Terminal descent thrusters can not spend any more
than a few hundreds of milliseconds within a meter or so of the surface without digging trenches, launching small rocks into the landing gear and producing destabilizing ground-effect backpressure on the bottom of lander. For this reason, legged landers with integrated propulsion systems approach the ground at relatively high speed (2.4 m/s) with the converse effect of increasing susceptibility to slope-induced tip-over hazards.

A surface clearance between 30 and 50 cm is believed to be sufficient for many scientifically interesting landing areas on Mars; however, the ability to directly detect rocks of that size from Mars orbit has not yet been accomplished (the current detection limit is > 1 m). Instead rock size distributions are inferred from the average thermal inertia of the landing area based on thermal response measured from the Viking IRTM, Mars Global Surveyor (MGS) TES and Odyssey’s THEMIS instruments. Large fractions of Mars show thermal inertias that are indicative of very rocky surfaces. Golombek et al\(^4\) have determined rock size distributions as a function of thermal inertia. With the arrival of the Mars Reconnaissance Orbiter, rocks larger than 0.5 m in diameter may become visible from orbit.

Large rocks can also be found in the vicinity of crater rims for unmodified craters larger than about 100 m in diameter. \textit{A priori} landing site selection practices attempt to limit the number of large craters (with diameters > 1 km) within the target landing ellipse; however, craters less than 1 km are very difficult to avoid when the target ellipse is on the order of 30 x 80 km or more. When rocks are combined with slopes on the scale of a lander, tip-over at touchdown and post-landed solar array deployment interference pose additional hazards. Slopes on scales larger than about 3 m at potential landing sites are barely visible using stereo and photoclinometry digital elevation maps derived from images from the MGS MOC narrow angle camera.\(^7\)

Larger scale surface features like hills, mesas, craters and trenches pose risks not only to the touchdown system, but also to the ground sensors. Radar altimetry and Doppler radar can be “spoofed” by slopes and other surface shapes. Touchdown targeting algorithms such as those used on MER and MPF can be tricked into releasing the lander early if the vehicle is descending over mesas, trenches or crater rims. Horizontal velocity errors may be induced when a wide beam from a Doppler radar measures surface-relative velocity over slopes.

When performing Monte Carlo simulations that include all aspects of EDL including all expected environmental variations, it is common to count the number of times the EDL system encounters conditions that exceed its design capability envelope. For legged systems, Mars surface variability causes the largest source of capability violations. For airbag systems, Mars wind variability (and its resultant affect on touchdown velocity) causes the largest source of capability violations. In both landing systems, environmental conditions result in 2-15% probability of a capability violation (and an associated probability of mission failure). In addition, non-propulsive landing systems options, airbags and other mechanical means, are
generally limited to landed masses of approximately 0.6 t due to the design and qualification challenges associated with these systems in uncertain, rock-abundant terrain.

C. Space Flight Qualification

Due to the short time span of Mars EDL (on the order of 5-8 minutes) and the added complexity of switching between units in flight, most key EDL subsystems are non-redundant (single-string). As a result, EDL systems must exhibit high intrinsic reliability in their design environment. Because an EDL end-to-end verification and validation test is not possible on Earth due to differences in the Earth’s atmosphere and gravity, substantial simulation is included as part of the flight project’s verification and validation process. This end-to-end simulation must be anchored in data obtained from each EDL component’s use in past flight projects or Earth-based testing. Unfortunately, the cost associated with reproduction of a Mars-relevant environment for hypersonic and supersonic EDL systems can be quite large. This qualification cost has limited the application of new EDL technologies to those that are derived from past missions with minor modification (argued as having substantial heritage) or qualified in ground-based facilities at a reasonably low cost for the individual project.

III. Past Landed Missions

The first Mars landing attempt (Mars 2) in late 1971 by the USSR was a failure; however, the second attempt later that same year (Mars 3) resulted in a partially successful landing and 20 seconds of transmission from the surface before permanently falling silent.

The five successful US landing attempts began in 1976 with the dual landing of Viking 1 and 2. The Viking mission and the EDL technology developed for Viking became the backbone for all US missions since. More than 20 years later in 1997, the Mars Pathfinder (MPF) team adapted entry and descent technology from Viking and merged it with the deceptively simple terminal landing architecture employed in 1971 by the Soviets. Most recently, the Mars Exploration Rover (MER) EDL system that landed the Spirit and Opportunity Rovers in early 2004 was a significant upgrade of the Mars Pathfinder EDL design. In the coming years, the Phoenix lander (2007), and Mars Science Laboratory (2009) will apply new variations on these EDL designs. Key entry, descent and landing parameters for past and upcoming U.S. Mars missions are summarized in Table 1.

The Viking missions of 1976 (see Fig. 5) were largely influenced by the design of lunar landers (Lunar Surveyor and Apollo) and were not constrained by today’s relatively small budgets. As such, the high cost to develop new aeroshell, thermal protection, supersonic parachute, Doppler radar and throttled descent engine systems was accommodated within the overall project cost. Viking’s low mass design choice was to use landing legs with small clearances for rocks. Radar altimetry and Doppler radar was used to detect horizontal velocity and monopropellant throttled engines were employed to
bring the lander to within $2.4 \pm 1$ m/s vertically and $<1$ m/s horizontally. These choices were made based on the science team evaluation that the selected Mars landing sites were relatively flat and rock-free. Once on Mars however, the Viking designers were surprised to see large rocks so close to the lander (see Fig. 6)
Fig. 6 Big Joe at the Viking 1 landing site. Big Joe, approximately 2 m long and 1 m high, is located approximately 8 m from the Viking 1 landing site. The Viking landers were designed with a 20 cm rock clearance.

Mars Pathfinder (MPF) in 1997 was influenced by the need for extreme cost savings (relative to Viking) and the design of past lunar and Mars landers as well as US Army payload delivery systems. MPF’s approach to reduce cost was to use the Viking entry and parachute systems (with passive attitude control) and low cost solid rocket engines that would protect the lander from a much larger range of touchdown velocities than legged landers could handle. This approach would also eliminate the need for horizontal velocity estimation with Doppler radar. The consequence of these design decisions was the need for a heavy and difficult-to-test 4-pi steradian airbag system that could handle initial vertical velocities as high as 16 m/s and horizontal velocities as high as 22 m/s with the potential for tens of bounces on rocks as high as 0.5 m and 30° slopes (see Fig. 7).

Fig. 7 Mars Pathfinder and MER airbags.

The MER missions, arising from the programmatic turbulence after the loss of two Mars missions in late 1999, were most largely driven by schedule. These missions (proposed in April 2000) were intended to use the MPF EDL design so that the schedule to the summer 2003 launch date could be achieved. There was no initial plan to modify the MPF EDL system. However, as further information was gained (50% higher suspended mass than MPF and higher than originally-anticipated winds), it was discovered that the MPF terminal descent heritage was not sufficient to deliver the MPF airbags to an acceptable velocity envelope. New horizontal control systems (inertial measurements and small solid rocket motors in the
backshell) and new horizontal velocity estimation using descent imagery were added to ensure sufficient EDL system reliability. In addition, the MPF airbags were redesigned and toughened to handle the higher mass of the payload, and to survive higher impact velocities, up to 26 m/s.

The Phoenix mission, planned for launch in 2007, (see Fig. 8) is based on the design of the Mars Polar Lander mission that was lost during its landing attempt in 1999.\(^\text{12}\) This mission was also driven by the need for cost savings. Relatively expensive horizontal Doppler radar velocity measurement was avoided by using canted multi-beam radar. Expensive throttled engines were avoided by using off-pulsed engines at high duty cycles. While not as tolerant of rocks and slopes as the MPF/MER touchdown system, the ability to find areas on Mars less rocky and with lower slope will allow Phoenix to land safely. Recent full-scale testing of the duty-cycle modulated propulsion system has demonstrated that the pulsed-mode engine firing is robust.

![Fig. 8 Phoenix Lander.](image)

The Mars Science Laboratory (MSL) landing system, planned for launch in 2009, forges new ground in touchdown system design.\(^\text{13}\) One of the major design constraints for propulsive descent landers (where the descent engines must fire very close to the ground) is to utilize a low surface pressure plume or to spend a minimum amount of time in the vicinity of the surface. These constraints are meant to avoid creating hazardous pits in the surface and throwing rocks and dirt on top of the delivered payloads. This minimum time descent is accomplished by descending as fast as the landing gear will allow. Unfortunately, this conflicts with the need for ground clearance of high rocks under the vehicle and slope tolerance. Positioning the terminal propulsion system and its propellant tanks under a rover also presents egress challenges to the landed system. The realization that the MPF/MER terminal descent propulsion system (the solid rocket motors) in the backshell suspended above the lander could be “upgraded” to throttled monopropellant engines resolved this conflict. By virtue of their relatively large distance to the surface, descent engines suspended above the payload could deliver the system to the surface with much lower velocity without a significant increase in propellant (see Fig. 9). This descent system (dubbed the Skycrane after its namesake helicopter) eliminates the need for a heavy landing system while at the same time providing increased
tolerance of the lander to slopes and rocks. In fact, MSL is planning to land the rover directly onto its wheels without modifying the design of the rover mobility system. The MSL EDL system has the potential to someday allow Mars landed payloads to be designed independent of EDL, much as launch vehicles are today.

![Fig. 9 The MSL skycrane descent sequence.](image)

### IV. Current EDL Technology Limits

Many of the EDL systems discussed in the previous section were originally developed as part of the focused technology development effort that preceded the Viking landings. In addition to the first planetary landings, the Viking program developed the 70-deg sphere cone aeroshell, the SLA-561V forebody thermal protection material and the supersonic disk-gap band parachute. With minor modification, these three EDL components have formed the backbone of all Mars EDL architectures since. As the Mars robotic exploration program strives to deliver more mass to higher elevation sites with improved landed accuracy, one might ask: how far can these and other Viking-era EDL technologies take us?

#### D. 70-deg Sphere Cone with SLA-561V Forebody TPS

A scaled variant of the Viking 70-deg sphere cone aeroshell (see Fig. 10) has been employed on every Mars landing mission due to its relatively high hypersonic drag coefficient (zero angle-of-attack hypersonic $C_D$ of approximately 1.68) and the existence of a broad set of aerodynamic performance data on this shape. This aeroshell configuration has been flown successfully along different entry trajectories and at angles-of-attack between 0 and 11 deg. A different aeroshell forebody shape will not have a significant impact on hypersonic drag coefficient and therefore can not be relied upon as a means to improve EDL performance.

An entry system’s deceleration and heating profile is governed by its hypersonic ballistic coefficient, which is defined by its mass, drag coefficient, and reference areas as:

$$\beta = \frac{m}{C_D A}$$
A low ballistic coefficient vehicle will achieve lower peak heat rate and peak deceleration values by decelerating at a higher altitude in the Mars atmosphere. This system will be characterized by more timeline margin for the subsequent descent and landing events. To reduce ballistic coefficient, systems engineers tend towards the largest aeroshell diameters possible, where this diameter is generally limited by physical accommodation within launch vehicle and/or integration & test facilities. Cost requirements of recent robotic missions (MPF, MER and Phoenix) have led to reliance on Delta II class launch vehicles whose launch shrouds have limited the aeroshell maximum diameter to 2.65 m. However, for the cost increment of the Atlas V class launch system, aeroshell diameters as large as 4.6 m may be considered.

To date, $\beta$ has ranged from 63 to 94 kg/m$^2$ (see Table 1). Since ballistic coefficient is a significant driver on parachute deployment altitude and the subsequent EDL events timeline, as landed mass is increased, the aeroshell diameter must also increase. It is for this reason, that the Mars Science Laboratory project has adopted a 4.6 m diameter 70-deg sphere cone aeroshell, where the 4.6 m diameter is a limit imposed by existing integration and test facilities.

For landed masses above the 0.75 t proposed for MSL, launch shrouds larger than any currently in existence or large increases in ballistic coefficient (up to density limits dictated by aeroshell packaging) will be required. Using the extraordinarily-high packaged density of the MER aeroshell as an upper-limit and noting that to first-order, $\beta$ increases linearly with diameter, the maximum $\beta$ for a 4.6 diameter 70-deg sphere cone aeroshell is approximately 153 kg/m$^2$. This is the largest $\beta$ one can imagine for robotic Mars systems over the next several decades.

While such a system may be designed to successfully transit the hypersonic flight regime, Figure 11 shows the impact of ballistic coefficient on parachute deploy altitude. Assuming a fixed time requirement for the subsonic descent to the surface allows for examination of the relationship between $\beta$ and landing site surface elevation. For ballistic entry, the parachute deploy altitude of the $\beta=153$ kg/m$^2$ case is 7.3 km lower than for the $\beta=63$ kg/m$^2$ case. The advantage of aerodynamic lift is also evident in Fig. 11, resulting in a potential increase of 4-5 km at parachute deployment. Fig. 11
trajectories assume an entry velocity of 6 km/s, nominal low-tau (0.3) mid-latitude atmosphere, a vertical L/D of 0.18, use of a 19.7 m diameter parachute deployed at Mach 2.1 with $C_D$ of 0.65, and a 15-s timeline from Mach 0.8 to 1 km (start of propulsive descent). Each trajectory has an entry flight-path angle selected to maximize parachute deploy altitude.

Once off-nominal effects are included, an approximate landing site elevation limit may be derived as a function of $\beta$ and vertical L/D. Applying 3-$\sigma$ dispersed atmospheric, aerodynamic and parachute targeting uncertainties, the landed site elevation capability is shown in Table 2 as a function of $\beta$. To deliver additional mass over that listed in Table 2 to a given surface elevation, one must either reduce the hypersonic ballistic coefficient of the entry system, reduce the altitude/timeline requirements of the subsequent EDL events, or introduce new decelerator technology to reduce the supersonic descent ballistic coefficient.

![Fig. 11 Ballistic and lifting (vertical L/D = 0.18) Mars EDL nominal trajectories for $\beta = 63$ and 153 kg/m$^2$.](image)

High $\beta$ vehicles and larger diameter aeroshells will also suffer from additional aerothermodynamic heating and uncertainty in the prediction of that heating due to radiative effects and transition to turbulence.\textsuperscript{14, 15} For such systems, the peak heat rate is likely to be located along the conical flank of the forebody, as opposed to the nose region of the vehicle; as a result, shear effects may be significant. This is a more difficult aerothermodynamic environment and aeroshell location to accurately replicate in ground-based testing, introducing additional uncertainty in the TPS qualification approach. As the heat rate increases above several hundred W/cm$^2$, the heritage of the SLA-561V material must be reaffirmed or a new material
qualified for flight. While not directly affecting the aeroshell shape, such a qualification program will likely be expensive and require upfront planning of the development schedule.

E. Supersonic, 16m Disk-Gap-Band Parachute

As shown in Figure 3, the terminal velocity of a Mars entry system is generally larger than a few hundred m/s. While this is much slower than the several km/s entry velocity, it is too large an impact velocity for a lander. As a result, all previous and currently planned EDL architectures deploy a supersonic parachute to increase the descent β and slow the vehicle to subsonic speeds before too much altitude is lost. Besides the added drag, the parachute also provides sufficient vehicle stability through the transonic regime and the marked increase in descent β allows for positive separation of the aeroshell forebody (heatshield), a critical step in reconfiguration of the system for landing.

Analogous to the 70-deg sphere cone, all of the Mars landing systems in Table 1 use parachute systems derived directly from the Viking parachute development program. In 1972, high-altitude, high-speed qualification tests of the Viking parachute in Earth’s atmosphere were successfully conducted in Mars relevant conditions. These tests showed the Viking parachute design would robustly deploy, inflate, and decelerate the payload in the expected flight conditions. Due to the expense of these tests, their like has not been attempted since. Instead, all subsequent Mars EDL systems including those planned in the foreseeable future rely on inflation qualification by similarity to the Viking design and focus on parachute strength qualification through lower-cost subsonic and static testing.

The Viking project selected a disk-gap-band (DGB) parachute, shown in Fig. 12, whose acronym directly describes the construction of the parachute from a disk that forms the canopy, a small gap, and a cylindrical band. The Viking parachute system was qualified to deploy between Mach 1.4 and 2.1, and a dynamic pressure between 250 and 700 Pa, considerable margin relative to the Viking flight values of Mach 1.1 and a dynamic pressure of 350 Pa. This system had a 16 m diameter.

Fig 12 Viking-derived parachute systems.
Post-Viking applications of the DGB design varied the size and relative proportions of the parachute to trade stability vs. drag, but were careful not to invalidate the Viking inflation qualification. The Viking, Mars Pathfinder, and Mars Exploration Rover parachutes all performed their functions admirably at deployment Mach numbers as high as 1.8 and a dynamic pressure as high as 780 Pa (See Fig. 13). Both MER and MPF used smaller diameter supersonic parachutes as they delivered less mass to the Mars surface.

![Graph showing Mach and dynamic pressure history for all successful inflation disk gap band parachutes in Mars relevant conditions.](image)

The Mars Science Laboratory has baselined a larger diameter supersonic parachute than the one flown on Viking. This increase in parachute size is required due to the large descent mass and also to maintain scaling with the aeroshell diameter used in the Viking qualification program. Fortunately, the Viking qualification program included a parachute test (19.7 m diameter) of the size planned for MSL, and so this Viking test result applies directly to the planned MSL parachute qualification.

The MSL payload mass of 0.75 t may be the largest payload capable of delivery with Viking-era parachute technology. As we look to larger, greater than 1 t delivered systems, we will break out of the Viking qualification regime with respect to parachute size due to the need for larger aeroshell diameters and rapid deceleration to preserve timeline. As depicted in Figure 11, higher β entry systems reach the parachute deployment Mach limit at significantly lower altitudes with an associated loss of timeline for the subsequent EDL events. So in addition to larger size, a higher deployment Mach number may also be required (perhaps as high as parachute material temperature limits will allow, approximately Mach 2.7). These greater requirements will mandate a new high-altitude supersonic qualification program to enable those missions. Such a qualification program will be expensive and require upfront planning of the development schedule.
Once subsonic conditions are achieved, a larger parachute that is less expensive to qualify can be deployed to reduce the velocity further and hence the requirements on the terminal descent system, as well as potentially provide added time for the lander reconfiguration and sensing events. For large mass landed systems, such staged parachute systems may provide compelling system benefits that outweigh their inherent complexity and risk.\textsuperscript{20-22}

F. Landed Accuracy

To date, no Mars entry system has utilized a real-time hypersonic guidance algorithm to autonomously adjust its flight within the Mars atmosphere. MPF and MER flew ballistic (non-lifting) entries, and as such had no means of exerting aerodynamic control over the atmospheric flight path. As such, the design landing footprints were relatively large (200 km in 3-$\sigma$ downrange for MPF and 80 km for MER). While Viking flew a lifting trajectory, it did not utilize this lift to adjust the vehicle’s flight path to real-time uncertainties in the entry navigation or atmospheric conditions, and instead flew a lift-up entry to improve the EDL timeline and mitigate concerns in regard to achieving the appropriate deceleration in the thin Mars atmosphere.

Using the Mars Pathfinder and MER entries as a baseline, the addition of improved approach navigation (e.g., delta-DOR, dual spacecraft tracking and optical navigation) can reduce the 3-$\sigma$ landed footprint of a ballistic entry to approximately 60 km in major axis. To improve landed accuracy further, atmospheric and aerodynamic uncertainties must be mitigated during the atmospheric flight.\textsuperscript{23}

The Mars Science Laboratory will take the first major step toward performing precision landing at Mars.\textsuperscript{3} Utilizing hypersonic aeromaneuvering technology and improved approach navigation techniques, this spacecraft should set down within 10 km of the specified science target. This is essentially an order of magnitude improvement over the Mars Pathfinder, MER and Phoenix ballistic entries. Such an advance is possible as a result of improved interplanetary navigation techniques and the qualification for flight of a lifting aeroshell configuration directed by an autonomous atmospheric guidance algorithm that controls the aeroshell lift vector during the high dynamic-pressure portion of atmospheric flight.\textsuperscript{23} In this manner, based on in-flight measurements of deceleration, the guidance algorithm can autonomously maneuver the vehicle towards a more or less dense atmosphere region, thereby accommodating off-nominal entry-state or atmospheric-flight conditions. While numerous guidance algorithms have been developed for use during hypersonic flight, this will be the first flight of a lifting entry vehicle directed by an autonomous atmospheric guidance algorithm at Mars. This is a major advancement of planetary exploration EDL technology.

With use of a low L/D aeroshell, an autonomous atmospheric guidance algorithm and an accurate IMU, the vehicle’s position error at parachute deployment can effectively be reduced to the navigation knowledge error at IMU initialization.
Given that the landed system is likely to drift (uncontrolled) for several km while descending under the parachute, this knowledge initialization error can be on order of a few km (with respect to inertial space) without being the largest contributor to the landed inertial position accuracy. It is important to realize that, on Mars, inertial position accuracy is insignificant and it is terrain-relative position accuracy that is desired. During parachute descent, surface imagery may be obtained and compared with on-board maps to determine surface relative position. Propulsion may now be used to significantly reduce the effect of chute drift and navigation knowledge initialization error on terrain-relative landed accuracy. In this manner, terrain-relative landed accuracy may be limited to local map-tie error.\textsuperscript{24}

V. Breaking Out Of The Viking EDL Technology Box: Implications For Future Robotic Missions

As discussed in the preceding section, landing a Mars payload of approximately 0.75 t at a landing site of +2 km MOLA elevation is stretching the limits of our Viking-era EDL technology. However, there are several EDL technologies that show promise to deliver additional mass to the Mars surface. Some of these technologies may prove to be required for advanced robotic science missions like the Mars Sample Return (MSR) and Astrobiology Field Laboratory (AFL).

To view this challenge, the physical constraints of EDL must be illuminated. As discussed in Section IV, one such constraint is the present supersonic parachute deployment dynamic pressure and Mach qualification region. This constraint region is shown in Fig. 14. The trajectory of a Viking-heritage entry, descent and landing system must pass into this region in order to deploy a supersonic parachute. In Fig. 14, this region is bounded by Mach 2.1 and Mach 1.1 on the upper right, and left, a dynamic pressure limit of 250 Pa on the top, 1200 Pa on the lower right and finally 5 km MOLA altitude on the bottom. The lower altitude limit is a surrogate for the descent timeline from parachute deployment to the ground. Unless the mission happens to be targeting a Mars region with relatively low landing site elevation, this 5-km altitude limit is slightly aggressive.

![Fig. 14 Supersonic Parachute Deployment Region, Subsonic Deployment Regions.](image)
Figure 14 also shows a lifting entry trajectory for a vehicle with vertical L/D of 0.18 and a β of 100 kg/m$^2$. This trajectory is similar to that proposed for the Mars Science Laboratory project. The trajectory travels right-to-left into the supersonic parachute deployment region before inflating a 19.7 m diameter parachute at Mach 2.1. Note that without a parachute, this entry system would impact the surface at approximately Mach 1 (dashed line). Figure 14 also depicts two other regions. The subsonic region is bounded by Mach 0.8 on the right, a dynamic pressure of 50 Pa on the left side, and 3 km MOLA altitude on the bottom. Subsonic parachutes must be inflated at or below Mach 0.8 due to drag loss near Mach 1. This is the region where aeroshell separations and deployments may occur. The subsonic propulsion region is bounded by Mach 0.8, a thrust-to-Mars-weight upper limit of 8 and a lower limit of 2. These constraints suggest several alternatives for the delivery of large mass payloads, which are discussed in the following sections:

1) Reduction in the hypersonic ballistic coefficient below 50 kg/m$^2$ through large increase in reference area.
2) Extension of the supersonic parachute deployment region to the right, to even higher Mach numbers.
3) Increased vertical lift without a reduction in drag.
4) Development of a new supersonic decelerator that can “capture” the entry vehicle state higher and faster.

A. Reduction in Hypersonic Entry Ballistic Coefficient

As mass grows, β will increase and the entry trajectory will eventually fall short of the supersonic parachute deployment region. Figure 15 shows the effect of increasing β from 25 to 200 kg/m$^2$ while fixing lift and entry flight path angle. When β gets above approximately 150 kg/m$^2$, the trajectories fall below the supersonic parachute deployment region and a Viking parachute cannot be used for aerodynamic deceleration. This is termed the “Supersonic Transition Gap” and implies large aeroshell diameter requirements for a large payload mass. Without significant modification of the hypersonic entry trajectory, high β entry vehicles cannot land on Mars.

One alternative is to decrease β and enter with a very large hypersonic decelerator. As shown in Fig. 15, blunt body entry vehicles with β on the order of 25 kg/m$^2$ eliminate the need for a separate supersonic decelerator. These systems would simply require a drogue for stabilization in the transonic regime and a large subsonic parachute or propulsive decelerator. For a 1 t lander, the aeroshell would have to be about 11.5 m in diameter. Without on-orbit construction, an inflatable or deployable entry aeroshell is a logical option. Full scale testing of these systems at Earth under Mars-like conditions will be required (at high altitude and at hypersonic speeds). While much work remains to qualify inflatable and deployable hypersonic entry aeroshells for Mars, this technology appears promising for larger mass robotic systems.$^{25}$ As an intermediate step, one could utilize an inflatable system below Mach 5 where the aeroheating environment is much lower than at hypersonic speeds.$^{26}$
B. Extension in the Parachute Deployment Region

Extension of the disk-gap-band inflation Mach region to Mach 2.7 or Mach 3 may be possible using stronger and more heat-resistant fabrics (see Fig. 16). The parachute structure would also have to be designed to higher inflation dynamic pressures (well above 1200 Pa). Low density, high Mach Earth tests have shown an indication of dynamic instability above Mach 2.5 that may require significant new high altitude and high dynamic pressure flight tests. In addition, if larger diameter parachutes were qualified, the lower bound of the parachute deployment region would be reduced, expanding the supersonic parachute deployment envelope. The Mars program has studied what it would take to develop and qualify a 30 m diameter Mach 2.7 disk-gap-band parachute. This parachute is 50% larger diameter and would provide 2.3 times the drag than the largest Viking chute ever tested. As it was in the 1960’s, this test program would be technically challenging and costly. While this development would likely enable the robotic MSR and AFL missions, other solutions must be found for missions that approach human scale exploration > 20 t.
C. **Supersonic Propulsion**

An additional supersonic decelerator possibility is simply to use propulsion. While this appears straightforward, there is little experience firing larger thrusters directly into a high dynamic pressure supersonic flow. Flow stability, flow-control interaction and thermal protection are some of the design issues that surround use of this technology. This technology development option may provide a strong link between advanced robotic landers and those required for eventual human exploration.

D. **Increased Vertical Lift of the Entry Body**

With additional vertical lift, a large mass entry system may be able to regain sufficient altitude to enter the Viking supersonic parachute deployment region. However, care must be taken to avoid designing in additional lift at the expense of drag area, and hence a corresponding $\beta$ penalty. Figure 17 shows the affect that increasing the vertical $L/D$ from 0.2 to 0.5 has on the trajectory. The addition of lift (without significant loss of drag) may allow entry vehicles with $\beta$ as high as 200 kg/m$^2$ and vertical $L/D$ greater than 0.2 to enter the supersonic parachute deployment region. Likewise entry vehicles with $\beta$ as high as 250 kg/m$^2$ with vertical $L/D$ greater than 0.25, and 300 kg/m$^2$ with vertical $L/D$ greater than 0.3 may be able to enter this region.

Parachute capability after supersonic inflation poses other constraints that may limit vehicle mass (and hence $\beta$). In particular, to provide sufficient time to configure the vehicle for landing before reaching the ground, the descent $\beta$ must be below 35 kg/m$^2$. This implies large parachute diameter requirements for high entry masses (high $\beta$ cases).

E. **The Next Steps in Mars Robotic EDL**

Robotic Mars missions in the 2010 decade will likely require larger landed mass than has been delivered to date. If these systems require delivery of 2 t on the Mars surface (or 1 t to high surface elevations), at least one of the above technology options will need to be exercised. It is likely that the parachute Mach and diameter option will be exercised first as these require extension of existing qualified technology; however, if studies and efforts for eventual human Mars EDL are prioritized, future robotic systems may be required to introduce greater technology leaps in preparation for an eventual landing of astronauts on Mars.
VI. Human Exploration EDL Reference Architecture and Technology Challenges

2010-decade target capabilities for robotic spacecraft include landing 1-2 t payloads with a precision of less than 10 km, at high altitude landing sites (+2 km MOLA). These capabilities are quite modest in comparison to the requirements of landing human crews on Mars, which may imply landing 40-80 t payloads with a precision of tens of meters, possibly at high altitude. New EDL challenges imposed by the large mass requirements of human Mars exploration include: (1) the need for aerocapture prior to EDL and associated thermal protection strategies, (2) large aeroshell diameter requirements, (3) severe mass fraction restrictions, (4) rapid transition from the hypersonic entry mode to a descent and landing configuration, (5) the need for supersonic propulsion initiation, (6) landing accuracy and surface-rendezvous imposed no-fly zones, and (7)
increased system reliability. In this section, an entry, descent and landing architecture for human Mars exploration is presented, highlighting the technology challenges and advances required.

A. Aerocapture

Aerocapture, a single-pass atmospheric maneuver designed to transfer directly from a heliocentric arrival trajectory into the proper Mars staging orbit, has been proposed for several robotic missions but never attempted (see Fig. 18). For robotic missions to Mars, it has been shown that the benefits of aerocapture are relatively small compared to an aerobraking mission. However, for human exploration, aerocapture followed by a subsequent entry and descent to the surface from orbit has several advantages, including significant mass reduction relative to propulsive orbit insertion, mission design flexibility, the ability to accommodate uncertain atmospheric conditions (e.g. dust storms), reduced peak entry deceleration for the human crew relative to direct EDL, and significant time savings relative to aerobraking. The operational flexibility gained from dwelling in orbit prior to landing mitigates the risk of atmospheric uncertainty. In addition, aerocapture is applicable to components of the human exploration architecture that never land on the surface, but instead dwell in Mars orbit for later rendezvous and Earth return. While aerocapture is an untried technology, it will likely be required for human missions to bring mass requirements into a feasible range.

A parametric study of aerocapture trajectories was performed to explore the design space for vehicles of a scale suitable for human exploration. Aerocapture trajectories may be constrained by several limits: (a) the trajectory with the most shallow flight path angle that meets the exit energy constraint (lift-down). This trajectory has the lowest peak heating rate and lowest peak deceleration, but the highest integrated heat load; (b) the trajectory with the steepest flight path angle that meets the exit energy constraint (lift-up). This trajectory has the highest peak heating rate and the highest peak deceleration, but the lowest integrated heat load; (c) the flight path angle that achieves the specified peak deceleration limit with a lift-up entry (5-g). The vehicle flies lift-up until peak deceleration, and after the limit is reached, uses bank angle...
control to achieve the desired exit energy. The 5 Earth-g limit was assumed to be the maximum tolerable deceleration for short periods by a crew of de-conditioned astronauts.\textsuperscript{28}

Figure 19 shows acceptable entry flight path angles for a vehicle with 100 t entry mass, diameter of 15 m and a lift-to-drag ratio (L/D) of 0.3. Note the significant increase assumed in aeroshell diameter relative to that discussed for the Mars robotic exploration program (factor of 3). Even with this increased diameter, it is of interest to note that this aerocapture system has a $\beta$ on the order of 400 kg/m\(^2\) (more than 2.5 times that deemed possible by the robotic program and more than 4 times that proven on Mars to date).

![Aerocapture corridor width as a function of Mars entry velocity for an L/D = 0.3. With current navigation technology assumptions, an L/D of 0.3 is sufficient for Mars aerocapture.](image)

The region of feasible trajectories is shaded in gray and is bounded by the constraints described above. The theoretical entry corridor, without regard to deceleration limits, is the area between the lift-down and lift-up curves. This is the corridor achievable only with regards to the aerodynamics of the entry. When the deceleration limits of the crew are considered, the 5-g lift up curve provides the lower bound on the space for all entry velocities above approximately 6.5 km/s, narrowing the available corridor. The corridor width requirement is set by the approach navigation performance. Recent robotic Mars missions have demonstrated the ability to meet flight path angle delivery requirements between ±0.25 and ±0.5°. For this study, a delivery accuracy requirement of ±0.5° was conservatively selected.\textsuperscript{28} This total entry corridor width of 1° determines the maximum entry velocity feasible for a particular vehicle configuration. From Fig. 19, an aerocapture L/D = 0.3 is sufficient (for an entry flight path angle requirement of ±0.5°) for Mars entry velocities under 9.1 km/s, a likely condition for most human Mars exploration architectures. Following aerocapture, the vehicle performs a small periapsis raise maneuver to insert into a parking orbit.
B. Entry from orbit

Once orbital operations are complete, the Mars crew initiates an entry-from-orbit sequence. A parametric study of entry-from-orbit trajectories was performed for vehicles of a scale suitable for human missions. Figure 20 depicts the altitudes at which the vehicle has slowed to various supersonic conditions for a range of potential entry masses, assuming a vehicle with L/D = 0.3 and 15 m diameter entering from orbit. These curves were utilized to assess where in the EDL profile to transition from hypersonic entry to supersonic deceleration via parachutes or propulsive descent. Figure 20 highlights how difficult it is to slow a human-scale vehicle with high ballistic coefficient (entry mass of 50-100 t) before impact with the surface due to the low-density Mars atmosphere.

![Fig. 20 Mach 4, 3 and 2 transition altitudes as a function of entry mass for a 15 m diameter aeroshell and a L/D = 0.3.](image)

As shown in Fig. 20, the initial conditions for the supersonic descent segment are strongly dependent on ballistic coefficient (entry mass). For a 15 m diameter aeroshell and 60 t entry mass, the vehicle reaches Mach 2 at 5 km altitude, about the minimum possible from a descent timeline perspective. However, a 100 t vehicle packaged within a 15 m diameter aeroshell does not reach Mach 2 until it is at the surface. Note that a Mach 3 aerodynamic decelerator may allow use of a 100 t entry system for human Mars exploration. In addition, the heavy dependence on ballistic coefficient tends to favor larger aeroshells, and aerodynamic shapes that have a high drag coefficient, with only modest impact on landing site elevation capability as a result of lift performance. As shown in Fig. 20, lift can increase the terminal entry altitude by 3-5 km (difference between the lift-up and lift-down entries).

C. Aeroshell shape and size

A 70° sphere-cone forebody (see Fig. 21) was assumed for this 15 m diameter aeroshell because its geometry is traceable to the Viking and subsequent robotic landers and this forebody shape provides a relatively high hypersonic drag coefficient. In this respect, capsules and other blunt shapes compare favorably to slender-body designs that offer lift and higher L/D at the expense of drag (and therefore final altitude). When flown at an L/D = 0.3, this configuration provides a
greater than 1° wide entry corridor for aerocapture velocities up to 9.1 km/s, with stagnation point peak heating rates on the order of 400 W/cm² and maximum decelerations in the range of 3 to 5 Earth g’s. In the entry-from-orbit mode, this configuration could provide the high drag necessary \( (C_D = 1.40, \alpha = 20°) \) to give the vehicle sufficient altitude at Mach 3 or 4 to perform the subsequent descent and landing events for entry masses in the range of 80–120 t. Note once again that this system has a \( \beta \) of 300-450 kg/m² (a factor of 3 to 4 higher than any vehicle flown to date in the robotic Mars exploration program).

**Fig. 21 70° sphere-cone aeroshell with \( L/D = 0.3 \), \( (\alpha = 20°, C_D = 1.40) \).**

From a vehicle packaging standpoint, a large blunt body design is flexible. The diameter is driven to 15 m by the need to accommodate high-volume components such as the surface habitat and descent stage. The capsule shape allows a large portion of the mass to be packaged near the front of the vehicle for improved hypersonic stability. The stability ratio (aft distance of center of mass divided by diameter) achieved for the packaged configuration was less than 0.35 (slightly less stable than current robotic designs). Since the lander is likely to transition to propulsive descent around Mach 3, aerodynamic stability problems at low supersonic Mach numbers are minimized.

The blunt body design also benefits from the fact that no vehicle reorientation is required during the EDL profile. In all flight regimes, acceleration is imparted to the vehicle in the same direction, thus facilitating the design of crew positions with respect to g-tolerance. In addition, no timeline is lost during the late stages of the EDL sequence to reorient the vehicle in preparation for propulsive descent.

Perhaps the largest EDL-imposed technical challenge inherent in such a mission architecture is the need for a heavy lift launch vehicle capable of lofting a 15-m diameter payload in one piece. Ultimately, this challenge must be weighed against the difficulty of launching a human-rated aeroshell in several pieces and then assembling and certifying it in LEO, developing inflatable/deployable aeroshell technology, or limiting the Mars exploration architecture to much smaller diameters and entry masses (through a surface rendezvous and assembly strategy).
D. Aerothermal design

Aerocapture and entry from Mars orbit produce very different aerothermal environments. The aerocapture peak heating rate for an 8.5 km/s arrival velocity is about 20 times higher than the peak heating rate for a 4 km/s entry from orbit and the total integrated heat load is 4 times higher. As a result, the thermal protection system (TPS) required for the two maneuvers is quite different.

The aeroshell TPS may be configurable for dual-use (aerocapture and EDL). In this case, the same aeroshell is used first for aerocapture, and later for entry. Three concerns arise from this approach. First, since the TPS must be sized for the harsher aerocapture environment, the vehicle performs its entry-from-orbit with a more massive, high ballistic coefficient heat shield than would nominally be required, exacerbating heating and deceleration concerns. This also depresses the altitude where the vehicle has slowed to its Mach 3 or 4 transition altitude. Second, following the aerocapture maneuver, if the vehicle does not jettison the aerocapture heat shield it must be designed to withstand a large amount of heat soaking back into the vehicle structure from the TPS. Extreme temperature cycles pose a structural design concern due to thermal expansion. Finally, a third challenge to a common aerocapture and entry TPS is the need to support the orbital functionality of a large crewed spacecraft without compromising the thermal protection system integrity for subsequent atmospheric maneuvers. Power, thermal, orbit-trim propulsion, attitude control, communications, and other spacecraft functions must be achieved from within the confines of the aeroshell, which implies that the backshell (and possibly the forebody) of the vehicle must allow openings for items such as solar arrays, radiators, engines, thrusters and antenna.

An alternate approach for the TPS configuration would be to use separate, nested heat shields for aerocapture and EDL. This provides the benefit of jettisoning the hot aerocapture TPS immediately following the aerocapture maneuver, and allows the use of much lighter TPS for entry, thus minimizing the vehicle’s ballistic coefficient for that maneuver. The disadvantage of this approach is that packaging two nested heat shields on the vehicle requires a means of securing the primary heat shield to the structure and separating it without damaging the secondary heat shield and likely results in an overall mass penalty. Additional work is required to assess these TPS configuration and mission operations options.

E. Supersonic propulsive descent

Following hypersonic entry, a vehicle intending to land on the surface of Mars must slow itself from supersonic velocities to a speed appropriate for a soft landing. This last deceleration phase, which involves only a few percent of the vehicle’s remaining kinetic energy, has been initiated in past robotic missions below Mach 2.1 using some combination of parachutes and rocket-propelled descent. From Figure 20, it is clear that a Mach 2 initiation of this phase is not sufficient for the high mass entry systems associated with human exploration. The total descent time from Mach 3 or 4 to landing is on the
order of two minutes. During this phase, several vehicle configuration changes are required. In a matter of seconds, the vehicle will need to re-orient itself, an aeroshell and/or back shell may be jettisoned, parachutes may deploy, engines may start, navigation and hazard avoidance sensors must operate, and landing gear may deploy. In this very dynamic phase of flight, robust event sequencing and timeline margin are critically important.

To date all parachutes utilized in the robotic Mars exploration program have been derived from the technology effort that led to the Viking flight project. These systems have been limited to diameters on the order of 10-20 m and supersonic deployments below Mach 2.1. As discussed in Section 5, in an effort to improve landed mass, the robotic exploration program may pursue a large diameter supersonic parachute, likely no larger than 30 meters and deployed at velocities below Mach 2.7 (in response to thermal constraints). As a result of the large masses involved, parachutes sized for human exploration systems would represent a significant departure (in both size and deployment Mach number) from their robotic counterparts. In addition, due to their size, such systems will require significant opening times. For example, to decelerate a 100 t vehicle from Mach 3 conditions to 50 m/s near the Mars surface would require a supersonic parachute diameter on the order of 130 m. Similarly, a 50 t vehicle requires a supersonic parachute diameter on the order of 90 m. While clustered supersonic chutes are an option, the size of such systems would still result in large timeline penalties for opening. As such, a parachute descent phase for Mars human exploration vehicles, similar to the concepts now used for robotic landers, is likely impractical.

Drogue parachutes (of similar diameter to the main chutes employed by the robotic program) may still be necessary to stabilize a vehicle supersonically or effect separation events, but the effect of a large vehicle disrupting the flow in front of the parachute can not be neglected since the size of the vehicle (15 m diameter) may be on the same order as the size of its parachute. Flow interactions around the parachute will be complicated further if drogue stabilization is required during propulsive descent. This possibility may arise if the descent engines, being clustered under the vehicle center of mass, lack sufficient moment arm to overcome aerodynamic torques at supersonic conditions.

Propulsive descent requirements were evaluated based on a gravity turn maneuver initiated at Mach 4, 3 or 2. The results included the \( \Delta V \), thrust-to-weight, and propellant mass fraction requirements. A 265 m/s allowance was made for a crossrange maneuver associated with landing next to a pre-emplaced asset without endangering it. Items varied in this trade study include vehicle mass, vehicle diameter, and whether or not the aeroshell was released before propulsive initiation. The trajectory flown was a simple constant-thrust gravity turn, followed by a lower-thrust terminal descent and landing. No attempt was made to find a more fuel-optimal descent profile, since other unmodeled considerations (e.g., range safety and landing re-designation) will contribute significantly to the propellant situation.
Figure 22 shows that propulsive descent from Mach 3 requires 1.0 – 1.25 km/s of velocity change, including the 265 m/s cross range maneuver. This figure shows that ballistic coefficient, while not a dominant factor, does play a role. A lower ballistic coefficient leads to very low thrust-to-weight ratios (< 0.5), longer flight times, higher gravity losses, and therefore a somewhat higher cumulative ΔV.

Figure 23 shows the propellant mass fraction (propellant mass/entry mass) required of a large Mars lander for two different values of specific impulse. Mass fractions typically fall in the range of 20-30%, for the propulsive deceleration and the 265 m/s cross range maneuver. Raising the specific impulse by 100 s lowered the propellant mass fraction by 5-7%. While an all-propulsive solution for decelerating from Mach 3 to landing requires a relatively large amount of propellant, it has the advantage of being insensitive to atmospheric uncertainty and to landing site altitude.

![Fig. 22 ΔV for propulsive descent from Mach 3.](image)

![Fig. 23 Propellant mass fraction for propulsive descent from Mach 3.](image)

While parachutes alone are inadequate for slowing large payloads at Mars, the all-propulsive solution results in high propellant mass fractions and requires aeroshell separation and propulsive descent initiation to take place at supersonic
speeds. As such, a trade study was conducted to quantify how a large, supersonic parachute could mitigate these issues. In this assessment, aggressive assumptions were made in regard to parachute deployment conditions (Mach 3) and altitude requirements for the subsequent descent and landing events. Figure 24 shows the parachute sizes required to decelerate a payload from Mach 3 to Mach 0.8 at an altitude of 2 km. A Mach number of 0.8 was chosen to mitigate the aeroshell separation and re-contact concerns of current robotic landers. Figure 24 shows that a 30 m, Mach 3 parachute allows for a subsonic propulsive deceleration maneuver if entry masses are below approximately 33 t. This same parachute can slow the vehicle to Mach 1.0 at 2 km for entry masses less than 50 t. For entry masses above 50 t, a larger chute is required (with a significant opening time penalty), or the propulsive deceleration maneuver must begin supersonically.

An additional benefit of this approach is that the parachute can be used to separate the payload from the aeroshell. Atmospheric uncertainty is a major driver for parachute-assisted descent. The results described above are for a nominal atmosphere. If a conservative density is modeled, the 30 m parachute is only practical for entry masses below approximately 20 t. Parachute assisted propulsive descent still requires significant propellant mass fraction to bring the vehicle from Mach 0.8 to a soft landing. Overall, the total propellant mass fraction required for descent and landing will decrease from 20-30% of entry mass for an all-propulsive system (see Fig. 23), to a range of 12-18% for a parachute assisted system.

Additional work is required to determine a feasible approach to transition from an entry to landing configuration supersonically. For the large mass entry systems associated with human Mars exploration, this transition is likely to be initiated at Mach 3 or 4. For this reason and due to extreme size requirements, parachute systems similar to the concepts now in use by robotic systems, are likely impractical, even when coupled with subsequent propulsive deceleration. Options for further study include large aerodynamic decelerators with robust functionality from Mach 3 or 4 to the surface and propulsive descent systems that are initiated supersonically.

Fig. 24 Parachute diameter as a function of entry mass for a parachute-assisted deceleration from Mach 3 to Mach 0.8 at an altitude of 2 km.
F. Pinpoint landing and no-fly zones

A human exploration landing system will require pinpoint landing capability, both for mission safety given the extreme variability of the Mars surface and to ensure rendezvous with pre-deployed exploration assets. In meeting these objectives, the human exploration entry system must approach the landing site on a trajectory that does not discard debris created during the EDL sequence (e.g., separated stages) upon the existing surface assets. In a Mars outpost strategy, most of these same requirements must be met by earlier robotic missions.

As discussed in Section IV, with use of a low L/D aeroshell, an autonomous atmospheric guidance algorithm and an accurate IMU, the vehicle’s position error at parachute deployment can effectively be reduced to the navigation knowledge error at IMU initialization. This error can be reduced below 1-km through use of advanced navigation techniques including optical navigation and spacecraft-to-spacecraft tracking. Even without these improvements, surface imagery may be obtained and compared with on-board maps to determine surface relative position and propulsive maneuvers may be used to null terrain-relative landed accuracy error. In this manner, as with the robotic program, terrain-relative landed accuracy may be limited to local map-tie error.24

VII. Concluding Remarks

The United States has successfully landed five robotic systems on the surface of Mars. These systems all had landed mass below 0.6 t, had landed footprints on the order of hundreds of km and landed at sites below -1.4 km MOLA elevation due the need to perform entry, descent and landing operations in an environment with sufficient atmospheric density. Robotic exploration systems engineers are struggling with the challenges of increasing landed mass capability to 1 t while improving landed accuracy to tens of km and landing at a site as high as +2 km MOLA elevation. Subsequent robotic exploration missions under consideration for the 2010 decade may require a doubling of this landed mass capability. To date, no credible Mars EDL architecture has been put forward that can safely place a 2 t payload at high elevations on the surface of Mars at close proximity to scientifically interesting terrain. This difficulty is largely due to the Mars program’s continued reliance on Viking-era space qualification technology.

In this investigation, the technology challenges associated with improving our landing site access and landed mass capability were reviewed. Approaches being investigated by the robotic Mars exploration program to increase landed mass capability to 1 t while improving landed accuracy to tens of km and landing at a site as high as +2 km MOLA elevation were described and it was shown that this class of mission may be the limit for the Viking-era EDL technology, which has served us so well.
EDL technology challenges emanate from (a) a Mars atmosphere, with significant variability, that is thick enough to create substantial heating, but not sufficiently low terminal descent velocity, (b) a Mars surface environment of complex rocks, craters, dust and terrain patterns, and (c) the high cost of replicating a Mars-relevant environment for space flight qualification of new EDL technologies.

Robotic exploration technology options that may greatly improve current EDL system delivery limits include larger diameter parachutes that deploy at Mach numbers as high as 2.7, inflatable/deployable aerodynamic decelerators that greatly reduce ballistic coefficient and pinpoint landing technologies focused on robust terrain-relative navigation.

This investigation also presented a potential entry, descent and landing sequence for Mars human exploration architecture, highlighting the technology and systems advances required. Unfortunately, it is concluded that Mars human exploration aerocapture and EDL systems will have little in common with current and next-decade robotic systems. As such, significant technology and engineering investment will be required to achieve the EDL capabilities required for a human mission to Mars. Promising technologies for human exploration EDL include inflatable/deployable aerodynamic decelerators that greatly reduce ballistic coefficient, supersonic propulsive descent systems and pinpoint landing technologies focused on robust terrain-relative navigation.

Additional refinement is required in the following human exploration EDL architectural areas: (a) assessment of aerocapture/entry TPS configuration options, and (b) an approach to efficiently transition from the entry to landing configuration at supersonic conditions within stringent timeline constraints. For the large mass entry systems associated with human Mars exploration, this transition is likely to be initiated at Mach 3 or 4. For this reason and due to extreme size requirements, parachute systems similar to the concepts now in use by the robotic exploration program, are likely impractical. Options for further study include large aerodynamic decelerators deployed hypersonically or supersonically and propulsive descent systems that are initiated supersonically.
