Algorithms and Sensors for Small Robot Path Following

Robert W. Hogg, Arturo L. Rankin, Stergios I. Roumeliotis, Michael C. McHenry, Daniel M. Helmick, Charles F. Bergh, Larry Matthies

Abstract—Tracked mobile robots in the 20 kg size class are under development for applications in urban reconnaissance. For efficient deployment, it is desirable for teams of robots to be able to automatically execute path following behaviors, with one or more followers tracking the path taken by a leader. The key challenges to enabling such a capability are (1) to develop sensor packages for such small robots that can accurately determine the path of the leader and (2) to develop path following algorithms for the subsequent robots. To date, we have integrated gyros, accelerometers, compass/inclinometers, odometry, and differential GPS into an effective sensing package. This paper describes the sensor package, sensor processing algorithm, and path tracking algorithm we have developed for the leader/follower problem in small robots and shows the results of performance characterization of the system. We also document pragmatic lessons learned about design, construction, and electromagnetic interference issues particular to the performance of state sensors on small robots.

Keywords—Mobile robots, path following, Kalman filtering, leader/follower, pure pursuit, localization.

I. INTRODUCTION

Mobile robots that are small and light enough to be carried in a backpack (i.e. “packbots”) by an individual have great potential to enhance the safety and effectiveness of urban reconnaissance and rescue operations. The size and weight of a recent prototype of such a robot is 60 x 50 x 17 cm and 20 kg. [1] Teams of these robots can be far more effective than individual robots for two reasons. First, a single robot cannot carry all of the sensor and effector payloads required for many missions. Second, multiple robots will often be necessary to cover multiple points of observation.

The need for multiple robots raises the problem of how to navigate them from the departure point to the objective with minimal burden on the human operator. Operator involvement is necessary to designate waypoints and intermediate objectives for the first robot; however, it is desirable for the rest of the robot team to automatically follow the path of the leader, without necessarily maintaining visual contact with each other.

Prior work on robot leader/follower behavior has used a variety of approaches, including visual motion tracking of the lead vehicle [2] and using INS/GPS systems to record the path of the leader, which is then traversed by the follower using the same sensors [3]. Methods depending on visual contact do not meet the needs of our application. Prior path following work based on INS/GPS has all been done on much larger vehicles. Hence, one of the main challenges for packbots has been to identify a sensor suite that would enable path following within the size, weight, power, and cost envelope of our vehicles. Other challenges include coping with GPS dropouts in urban areas and under tree canopies, coping with obstacles that fall within the positional uncertainty of the path following system, and enabling path following through constrictions that require greater positional accuracy than is available from the INS/GPS sensors. An example of the latter is following a path that leads through a culvert.

We are developing a leader/follower system that addresses all of the above challenges [4]. We have completed a path following system based on a Kalman filter which integrates an IMU, differential GPS, compass/inclinometers, and wheel encoder data. Obstacle avoidance is achieved with an arbiter-based architecture that combines steering votes from the path following behavior with steering votes from a stereo vision-based obstacle avoidance behavior.

Section II describes the navigation sensors that we selected and integrated into the robot. Section III describes the structure of our pose estimation Kalman filter. Section IV outlines the architecture of our leader/follower system and describes our path following control algorithm. Experimental results are shown in section V. We discuss the significance of the results, highlight open issues, and outline the extensions we have in progress in section VI.

Fig. 1. The packbot vehicle.
II. NAVIGATION SENSORS

The primary constraints for the navigation payload are accuracy, size, and power: the sensors must fit within the space and power budgets afforded by the chassis while delivering the resolution to reliably determine the position of the robot. Since the packbot is an autonomous platform, all perception, computation, and power resources are carried on board. The packbot is built upon the Urban II platform (shown in Figure 1) developed by iRobot Corporation. The chassis is approximately 60cm long, 50cm wide and 17cm tall with roughly 13,000cm³ of contiguous payload space. A 20-cell NiCd battery pack provides a total energy storage of 120Wh. Power consumption with the robot motionless is approximately 75W, and the power required for driving varies with the terrain. The robot and all subsystems must be able to survive the shock of being thrown or dropped modest distances.

Autonomous path following and generation requires that both the leader and the follower have tight control over their respective positional accuracy. The accuracy of the navigation sensors directly limits the robot’s ability to follow a path precisely. The accuracy limit and resolution is dictated by the terrain and by the follower’s level of autonomy. If it is desired to have a follower blindly weave through a series of tightly spaced obstacles, i.e. trees, then the accuracy of the estimated position needs to be high - roughly half the width of the robot. On the other hand, if it is desired to have a reactive follower weave through the same obstacles, the accuracy requirements can be relaxed.

In order to meet the requirements of operating in such varied and unstructured environments, a combination of GPS and inertial sensors is used.

A. GPS Receivers

Several commercially available GPS receivers were considered. For this application, both the differential and the real-time kinematic features are needed. The NovAtel Millennium RT-2 was selected for the initial system and has performed well. We found that heat generation and large turn-on transients (~5A) were a problem with this receiver. To solve these problems, we plan to migrate to a card that uses less power.

B. Inertial Navigation Sensors

Different IMU packages have also been studied throughout this program. At the start of the work, no integrated system was available which would fit into the payload. Therefore a system was built from separate components.

A TCM2-50 compass/inclinometers from Precision Navigation provides compass heading and absolute tilt and roll estimates. Three orthogonally mounted QRS11-200 rate gyros from Systron Donner and an EGCS3 three-axis accelerometer from Entran are used to measure angular rates and inertial forces. Careful consideration has to be given to the entire signal path from the sensor to the analog-to-digital converter. Initially, excessive noise in the signal caused the perceived drift rate to increase dramatically. Several steps were taken to reduce the noise including separating and isolating power supplies solely for the gyro and accelerometers, isolating the power and signal traces on the sensor and control board, shielding the signal traces, and taking special care of the routing of the signal traces to avoid cross-talk between the axes.

Since the beginning of the program, fully integrated MEMS inertial measurement units have become available. Their digital output eliminates the need for an analog-to-digital converter and increases noise immunity. These sensors are much smaller, requiring a half to a quarter of the volume of conventional integrated systems. Additionally, these units are being packaged with magnetometers so that a complete Attitude Heading Reference System (AHRS) solution is possible.

III. POSITION ESTIMATION

Precise localization is one of the main requirements for the task of autonomous path following. The packbot mobile robot is equipped with differential GPS (DGPS) that provides position estimates with 2-20cm uncertainty under favorable conditions. These uncertainties can become much higher when operating near buildings or trees, which occlude satellite signals making GPS navigation unreliable. During GPS dropouts, the signals from the inertial sensors, compass/inclinometers, and motor encoders have to be appropriately combined so as to determine the location of the robot until the next GPS update. By integrating accurate estimates of its linear and rotational velocity the packbot could potentially track its pose for a long period of time. However the robot’s skid steering has inherent slippage which makes the estimates based on the motor encoder signals untrustworthy, particularly rotational velocities.

Appropriate integration of the gyroscope signals (angular rates) provides estimates of the roll, pitch and yaw angles that determine the attitude of the vehicle. A common difficulty found in all approaches that rely on gyros for attitude estimation is the low frequency noise component (also referred to as bias or drift) that violates the white noise assumption required for standard Kalman filtering. Inclusion of the gyro noise model in a Kalman filter by suitably augmenting the state vector has the potential to provide estimates of the sensor bias when the observability requirement is satisfied. The system becomes observable when absolute orientation measurements are available. In the case of the packbot, this information is provided by the compass/inclinometers module. The inclinometers measure the attitude of the robot with respect to the horizontal plane while the compass provides a measurement of the direction of the vehicle compared to the magnetic north.
A. Noise Model for the Systron Donner Quartz Gyro

In the information provided in [5] it is obvious that the Systron Donner gyro does not have a stable bias. From page 1-4: "Low Rate Application - These gyros showed reasonable performance for rate scale factor stability but would not be useful for applications where bias stability was of high importance to meet mission requirements. The bias changed significantly as the input rate was changing making predictable bias compensation very difficult".

Long term bias stability data were gathered to create a stochastic model useful for attitude estimator performance prediction. This model assumes that the gyro noise is composed of 3 elements, namely: rate noise \( n_r(t) \) (additive white noise), rate flicker noise \( n_f(t) \) (generated when white noise passes through a filter with transfer function \( 1/\sqrt{s} \)) and rate random walk \( n_w(t) \) (generated when white noise passes through a filter with transfer function \( 1/s \)). The Power Spectral Density (PSD) of the gyro noise was measured experimentally and the logarithmic plots of the PSD with respect to frequency were used to fit the described model. The intensities calculated (ignoring the flicker noise) were: \( \sigma_r = \sqrt{N_r} = 0.009 \) \( \text{deg} / \text{sec} / \sqrt{Hz} \) and \( \sigma_w = \sqrt{N_w} = 0.0005012 \) \( \text{deg} / \text{sec} / \sqrt{Hz} \).

Based on this model [6] the angular velocity \( \omega \) is related to the gyro output \( \omega_{in} \) according to the equation:

\[
\omega = \omega_{in} - \dot{b} - n_r \\
E[n_r(t)] = 0 \\
E[n_r(t)n_r(t')] = N_r \delta(t-t')
\]

where \( \dot{b} \) is the drift-rate bias and \( n_r \) is the drift-rate noise assumed to be a Gaussian white-noise process. The drift-rate bias is not a static quantity but is driven by a second Gaussian white-noise process, the gyro drift-rate ramp noise:

\[
\dot{b} = n_w \\
E[n_w(t)] = 0 \\
E[n_w(t)n_w(t')] = N_w \delta(t-t')
\]

These two noise processes are assumed to be uncorrelated (\( E[n_w(t)n_r(t')] = 0 \)).

B. TCM2-50 Compass/Inclinometers Characterization

The TCM2 compass is comprised of 3 orthogonal magnetometers that measure the local intensity of the magnetic field of the earth. This information combined with the inclinometers' tilt angles - determined by the effect of the local vector of gravity on the contained viscous fluid - provides an absolute measurement of the attitude of the vehicle at a rate of 16Hz. The expected accuracy is \( \pm 1.5^\circ \) for heading and \( \pm 0.4^\circ \) for tilt. These measurements are processed by the Kalman filter in order to estimate the gyroscopes' biases and reduce their influence on the orientation estimates.

Since the compass is affected by local magnetic fields present on the robot, it has to be calibrated in order to compensate for static fields. However, such procedure cannot deal with the dynamic fields produced by the metallic belts inside the tracks of the robot. Experimental testing of the compass while manually rotating the tracks has shown variances of over \( 130^\circ \) (Figure 2). Now, nylon belted tracks are used whenever possible in order to avoid this problem.

C. Kalman filter based attitude estimation

C.1 Dynamic Model Replacement

In our implementation of a Kalman filter observer which, estimates the orientation of the robot, we employed sensor modeling instead of dynamic modeling. The main reasons for this are: (i) dynamic modeling would have to be redone every time there is a modification to the robot, (ii) dynamic model based observers require a large number of states that increases the computational needs without producing superior results [7].

C.2 Attitude kinematics and error state equations

The three-parameter Euler angle representation has been used in most applications of the Kalman filter in robot localization [8], [9]. However the kinematic equations for Euler angles involve non-linear and computationally expensive trigonometric functions. The computational cost using quaternions is less than using Euler angles. It is also more compact because only four parameters, rather than nine, are needed. Furthermore in the Euler angle representation the angles become undefined for some rotations (the gimbal lock situation) which causes problems in Kalman filtering applications. Amongst all the representations for finite rotations, only those of four parameters behave well

obtain part for tational with is.

The physical counterparts of quaternions are the rotational axis $\hat{n}$ and the rotational angle $\theta$ that are used in the Euler theorem regarding finite rotations. Taking the vector part of a quaternion and normalizing it, we can find the rotational axis right away, and from the last parameter we can obtain the angle of rotation [11]. Following the notation in [12] a unit quaternion is defined as:

$$ q = \begin{bmatrix} \hat{q} \\ q_4 \end{bmatrix} = \begin{bmatrix} \sin(\theta) \\ \cos(\theta) \end{bmatrix} $$

with the constraint $q^Tq = 1$, $\hat{n} = [n_x, n_y, n_z]^T$ is the unit vector of the axis of rotation and $\theta$ is the angle of rotation.

The rate of change of the quaternion with respect to time is given by:

$$ \frac{d}{dt} q(t) = \frac{1}{2} \Omega(\vec{\omega}(t))q(t) $$

where $\vec{\omega} = \vec{\dot{\theta}}$ is the rotational velocity vector. At this point we present an approximate body-referenced representation of the error state vector. The error state includes the bias error and the quaternion error. The bias error is defined as the difference between the true and estimated bias.

$$ \Delta \hat{b} = \hat{b}_{true} - \hat{b}_i $$

The quaternion error here is not the arithmetic difference between the true and estimated (as it is for the bias error) but it is expressed as the quaternion which must be composed with the estimated quaternion in order to obtain the true quaternion. That is:

$$ \delta q = q_{true} \otimes q_i^{-1} \iff q_{true} = \delta q \otimes q_i $$

The advantage of this representation is that since the incremental quaternion corresponds very closely to a small rotation, the fourth component will be close to unity and thus the attitude information of interest is contained in the three vector component $\delta \hat{q}$ where

$$ \delta q \approx \begin{bmatrix} \delta \hat{q} \\ 1 \end{bmatrix} $$

Starting from equations:

$$ \frac{d}{dt} q_{true} = \frac{1}{2} \Omega(\vec{\theta}_{true})q_{true} $$

and

$$ \frac{d}{dt} q_i = \frac{1}{2} \Omega(\vec{\theta}_i)q_i $$

where $\vec{\theta}_{true}$ is the true rate of change of the attitude and $\vec{\theta}_i$ is the estimated rate from the measurements provided by the gyros, it can be shown [13] that

$$ \frac{d}{dt} \delta \hat{q} = [\vec{\omega}_m] \delta \hat{q} - \frac{1}{2} (\Delta \hat{b} + \hat{n}_r) \quad \frac{d}{dt} \delta \hat{\theta}_i = 0 $$

Using the infinitesimal angle assumption in Equation (3), $\delta \hat{q}$ can be written as

$$ \delta \hat{q} = \frac{1}{2} \delta \hat{\theta}_i $$

and thus Equation (10) can be rewritten as

$$ \frac{d}{dt} \delta \hat{\theta}_i = [\vec{\omega}_m] \delta \hat{\theta}_i - (\Delta \hat{b} + \hat{n}_r) $$

Differentiating Equation (5) and making the same assumptions for the true and estimated bias as in the previous section (Equations (2) and (3)), the bias error dynamic equation can be expressed as

$$ \frac{d}{dt} \Delta \hat{b} = \hat{n}_w $$

Combining Equations (12) and (13) we can describe the error state equation as

$$ \frac{d}{dt} \begin{bmatrix} \delta \hat{\theta}_i \\ \Delta \hat{b} \end{bmatrix} = \begin{bmatrix} [\vec{\omega}_m] -I_{3 \times 3} \\ 0_{3 \times 3} \\ 0_{3 \times 3} \\ I_{3 \times 3} \end{bmatrix} \begin{bmatrix} \delta \hat{\theta}_i \\ \Delta \hat{b} \end{bmatrix} + \begin{bmatrix} -I_{3 \times 3} \\ 0_{3 \times 3} \\ 0_{3 \times 3} \\ I_{3 \times 3} \end{bmatrix} \begin{bmatrix} \hat{n}_r \\ \hat{n}_w \end{bmatrix} $$

or in a more compact form

$$ \frac{d}{dt} \Delta \hat{x} = F \Delta \hat{x} + \hat{G} \hat{n} $$

This last equation describes the system model employed in the current Kalman filter implementation [13]. This estimator combines the gyroscopes angular rates with the absolute orientation measurements from the compass/inclinometers in order to estimate both the attitude of the vehicle and the gyro biases. As shown in [14], this estimator acts as a high pass filter on the gyro signals by filtering out the low frequency noise component (bias) while weighing more their contribution during high frequency motion when the compass/inclinometers are susceptible to disturbances. If absolute orientation measurements are available continuously, the filter is capable of continuously tracking the gyro biases. In our case the robot uses the compass only when stopped, therefore the filter updates its estimate of the bias (Figure 3) only intermittently based on its effect on the attitude estimates during the previous interval of motion. The resulting attitude estimates (Figure 4) are then combined with the translational velocity measurements from the motor encoders to provide position estimates in between GPS updates.\(^2\)

\(^2\)We are in the process of enhancing the current Kalman filter implementation so as to fuse data from the accelerometers and the GPS and provide improved position estimates.
IV. SYSTEM ARCHITECTURE AND LEADER FOLLOWER CONTROL

A. System Architecture

The system architecture used to control the packbot is designed to allow multiple behaviors to command the robot simultaneously. The driving commands from these behaviors are arbitrated upon, and from them a final command is composed. This allows several behaviors using multiple sensors and imagers to work together effectively to carry out the commanded mission goals (see Figure 5). The navigation sensors are managed by device drivers which pass data through a software message queue to a single software task which carries out the necessary calculations. This task runs the Kalman filter and position estimation algorithms after each piece of sensor data comes in. It then updates the current state of the robot in a shared memory space where other tasks can access it. Currently the GPS is used to determine the robot's position both for recording and following paths. However when the robot is indoors, or when it drives into GPS-dropout areas, the position estimation is calculated with a simple interpolation using the Kalman-filtered heading and a raw odometry estimate from the wheel encoders.

The path recording and path following code, as well as other software tasks, can access the latest robot position and orientation estimates at variable rates and make decisions accordingly. A software task monitors the robot's current position and records a 3-D point after a certain constant offset has been passed thereby forming the robot's trail from successive points. The robot's trail is accessed, downloaded, and then edited using the Operator Control Unit, a GUI running on a laptop that is used to control and test the packbot. The modified or whole trail is sent to another robot or back to the same packbot, which accepts the trail and passes it to the path following module.

B. Path following control algorithm

Path following steering control is based on a carrot-following approach. A set of subgoals is transmitted to the follower vehicle. The follower vehicle uses the last two subgoals to extend the path sequence backwards, as shown in Figure 6. The follower vehicle then uses this extended path segment to locate a carrot position that lies a lookahead distance $L$ away from the vehicle center. The carrot position is updated every cycle by the path following algorithm. At any given instant, the follower assigns the largest weight to the arc that passes closest to the carrot.

The carrot is located by finding the intersection of a circle (centered at the vehicle center with radius $L$) and the
extended path segment. If there are two intersections, the one beyond the lateral position is chosen. If there is no intersection, the lateral position is chosen as the carrot. The steering curvature that will move the vehicle center directly over the carrot position is chosen as the commanded curvature.

C. Pure Pursuit Controller

The authors have experimented with two controllers that produce command curvatures: pure pursuit and proportional-integral-derivative (PID) control. Pure pursuit has been widely used as a steering controller for autonomous vehicles [15], [16]. Amidi and Thorpe [17] compared pure pursuit with a quintic polynomial fit method and a classic control theory approach. Ollero and Heredia [18] analyzed the stability of the pure pursuit algorithm for path following at constant speed (3, 6, and 9 m/s) for straight and constant curvature path sections, estimating the time lag for computing, communications, and actuator delay. Kelly [16] has described an adaptive pure pursuit controller, allowing the look-ahead gain to increase as a function of the lateral path error. Rankin [19] has evaluated a pure pursuit controller, a PI controller, and a weighted pure pursuit/PI controller.

The controlling equation for pure pursuit is shown in Equation (16). $k_{pure\:pursuit}$ is the command curvature and $y_{carrot}$ is the y coordinate of the carrot position as measured in the vehicle coordinate system. Pure pursuit is a proportional controller, where, $y_{carrot}$ represents the current error and $(2/L^2)$ represents the proportional gain. The lookahead distance L should be appropriate for the mission speed.

$$k_{pure\:pursuit} = \frac{2}{L^2} y_{carrot} \quad (16)$$

D. PID Controller

The second method of steering control that was implemented is a proportional-integral-derivative (PID) controller, as applied to the error in the vehicle’s heading. The idealized equation of a PID controller is shown in Equation (17). PID control contains a term that is proportional to the error, one that is proportional to the integral of the error, and one that is proportional to the derivative of the error [20].

$$k_{PID}(t) = G \left[ e(t) + \frac{1}{T_I} \int_0^t e(\tau) d\tau + T_D \frac{de(t)}{dt} \right] \quad (17)$$

The integral term acts as a spring (in a spring-mass-damper system) in that it eliminates steady state error. The derivative term acts as a damper. The parameters that are characteristic to the system are the proportional gain $G$, the integral time $T_I$, the derivative time $T_D$, and the sampling time $T$. For small sample times $T$, the idealized equation can be written as a nonrecursive difference equation, as shown in Equation (18).

$$k_{PID,n} = G \left[ e_n + \frac{T}{T_I} \sum_{i=0}^{n-1} e_i + \frac{T_D}{T} (e_n - e_{n-1}) \right] \quad (18)$$

The heading error $e_n$ is calculated by finding the orientation of the vector from the vehicle’s control point to the target position with respect to the axis in the direction of the vehicle’s current heading. A positive error results in a left turn and a negative error results in a right turn. Equation (18) can be rewritten as the difference equation

$$k_{PID,n} = k_{PID,n-1} + q_0 e_n + q_1 e_{n-1} + q_2 e_{n-2} \quad (19)$$

where,

$$q_0 = G \left[ 1 + \frac{T_D}{T} \right] = g_P + \frac{g_D}{T}$$

$$q_1 = G \left[ 1 + 2 \frac{T_D}{T} - \frac{T}{T_I} \right] = -g_P - \frac{2g_D}{T} + g_I T$$

$$q_2 = G \left[ \frac{T_D}{T} \right] = g_D$$

The PID controller works to force the heading error to zero so that the vehicle is always pointed towards the current carrot position. The parameters $g_P$, $g_I$, and $g_D$ are respectively proportional, integral and derivative gains. When $g_D = 0$, the PID controller is reduced to a proportional-integral (PI) controller.

E. Combined Pure Pursuit/PID Control

Both the pure pursuit and PID methods of steering control have advantages and disadvantages. The pure pursuit controller is easy to tune and performs well when the follower vehicle is started on or near the extended path segment. If the lateral path error is large, however, this method
can become unstable. Stability can be improved by using
an adaptive pure pursuit controller. With the adaptive ver-
sion, the look-ahead distance is a function of the lateral
path error. The adaptive controller, however, can cause a
significant portion of the path segment (traversed by the
leader vehicle) to be ignored by the follower vehicle.

The PID method is stable (when adequately tuned) over
the range of heading errors. This includes the scenario
where there is a large lateral path error. This controller
does, however, cause an inherent lateral path error when
travelling around curves. In an attempt to combine the de-
sirable features of both the standard pure pursuit and PID
controllers into a single controller, the output of each con-
troller is averaged, as shown in Equation (20). The arc
that is closest to this curvature is then assigned the largest
weight.

\[ k_{\text{command}} = \frac{k_{\text{pure pursuit}} + k_{\text{PID}}}{2} \quad (20) \]

V. EXPERIMENTAL RESULTS

A. Indoor Testing

The path following algorithm is currently being run at
a rate of 10 Hz which is the same rate at which the po-

tion estimate is updated using either odometry or GPS
data. Due to the reporting speed of the inertial navigation
sensors, the Kalman filter updates the heading at over 256
Hz. During all tests the robot traversed the paths at a speed
of 50cm/sec. To provide enough detail to describe the path
without accumulating an unnecessary number of points, an
interval of approximately 20 cm between points was used
to record the robot’s trail.

Initially, several indoor runs were used to test the fol-
lower algorithm and tune its parameters. Figure 7 shows
a path recorded by the packbot and the three separate path
following runs carried out by the same robot using the dif-
ferent control methods (pure pursuit, PID, and the combi-
nation of the two). In the indoor tests no GPS data could
be received so all position estimates used the Kalman filter
heading and odometry from the wheel encoders. This also
means that only relative robot coordinates were known so
even though the start and finish of the runs are at the same
points in the graph, in actuality the robot was possibly start-
ing in very different locations.

The pure pursuit method tended to oscillate over the
path being followed more than the PID but it also managed
to stay closer to the path in general. The PID control kept
the robot’s heading going in a parallel direction with the
path but maintained a slight offset for longer period of time
than the pure pursuit control. Currently work is being done
to tune the PID controller to better suit the packbot system.
The average of the controller error was used as a numerical
measure of the performance of each algorithm across vari-
ous runs. The simple combination of the two controllers
consistently reported the lowest controller-error averages.

B. Outdoor Results

In outdoor runs the packbot again was used to trace a
path and then was given its own trail to follow. During
these tests the Kalman filter provided the robot’s heading
and the GPS gave position data. While in motion the com-
pass/inclinometers noise is higher and thus the Kalman filter
relies more on the gyro package for heading approxima-
tion.

In Figure 9 a GPS dropout is indicated. When driving
under the obstacle, a small SUV, all GPS data was cut off
and the robot position estimator had to rely on the Kalman
filter heading and wheel odometry exclusively. Using this
method the recorded trail was interpolated through the GPS
dropout smoothly and the packbot was able to follow the
path up to, under, and past the obstacle without any not-
iceable problems. The GPS data converged approximately
10-14 secs after leaving the dropout area at which point the
position estimator switched back to using it to report the
packbot’s location.

VI. SUMMARY AND EXTENSIONS

In summary, we have integrated three-axis gyros and
accelerometers, a compass/inclinometer package, track
odometry, differential GPS, and an indirect, error-state
Kalman filter into a sensor system for small robot position
estimation. We summarized problems that arose with these
sensors and the solutions we found. Our sensor survey in-
cluded integrated IMUs that will soon be on the market.
These are smaller than the combination of sensors used
here and have advertised performance specifications that
are at least as good as the sensors we use now; these IMUs
are attractive for future systems.

In the leader/follower behavior, we implemented three
versions of the path following controller: pure pursuit, PI,
and an average of the two. Indoor and outdoor experiments over up to roughly 40 meters showed good performance for all three controllers, with maximum path deviations on the order of 50 cm. This included segments where the path went under vehicles that caused GPS dropouts. The averaging controller showed better error performance than either pure pursuit or PI alone.

In future robot systems and experiments, position estimation performance may be worse than reported here due to larger areas of GPS dropout or the use of smaller, lower cost GPS units with poorer precision. We are currently extending our system to include path smoothing to address GPS dropouts and to include special-purpose landmark recognition for path following through constricted areas of known types, eg culverts and doorways. We are also pursuing more general outdoor mapping and landmark recognition algorithms to further reduce the reliance on GPS.
