Time-resolved infrared methods can provide important information on the rates and mechanisms of atmospheric reactions involving transient species such as peroxyl radicals and short-lived intermediates. We have recently implemented two such methods in our laboratories: near-IR FM kinetic spectroscopy (IRKS) and mid-IR cavity ringdown spectroscopy (IR-CRDS). The former technique has been used as a high-sensitivity probe for HO₂ radicals to study reactions such as HO₂ + HO₂ → products, CH₃O₂ + CH₃O₂ → products and HO₂ + CH₃O₂ → products. While these reactions have been studied several times previously, the high sensitivity of the IRKS method has provided new insights into their rates and mechanisms. The implications of the results for the atmospheric formation of H₂O₂ will also be discussed.

The IR-CRDS technique has been employed to study the reactions

OH + NO₂ + M → HONO₂ + M

→ HOONO + M

Gas-phase infrared spectra of HOONO have been obtained for the first time in the region of the OH fundamental, and branching ratios for the two product channels have been obtained as a function of temperature. These results will be compared with predictions based on the kinetics of OH disappearance at high pressure.
